In the case of a spectacle lens of asymmetrical refraction (sphericocylindrical, toric), with the two principal meridians horizontal and vertical, respectively, the coefficients of increase in the power of the tilted lens are the same as in the case of a spherical lens, noting, however, that D [1], which we may write Dh, now represents the normal power of the lens in its horizontal meridian, and D [2], which we may write Dv, now represents the normal power of the lens in its vertical meridian.

In the case of a plano-cylindrical (or other equivalent) lens with the axis of the cylinder vertical, we have Dv = 0 [2], the effective power of the tilted lens increasing as shown in [1]. Taking the axis of the cylinder horizontal, we have Dh = 0 [1], the effective power of the tilted lens increasing as shown in [2].

For a full discussion of the case of oblique centrical refraction through any spherical lens, see Parkinson's Optics, iv., 68; for an extension of the discussion to principal cases of oblique centrical refraction through plano-cylindrical, sphericocylindrical, and toric lenses, see two communications, by the writer, in Transactions Am. Ophthalmological Society, 1890 and 1895.

Fashion has played its part in determining the shape of spectacle glasses; the original shape was doubtless circular, but that now generally preferred is a nearly regular oval. Another and, in some respects, preferable form is oblong, with rounded angles (Fig. 4336). A parallelogram with the four corners cut off by straight lines (octagon glasses) was a favorite shape a generation or two ago, and, though rather ungraceful, is still occasionally seen. Pulpit spectacles, so called, have the upper part of the rims flattened, in order to permit the wearer to see over them in looking at distant objects; the glasses are also set, as a rule, obliquely to the direction of the side pieces, but approximately perpendicular to the direction of the visual axes in reading. In ametropia, with defective accommodation, it is often convenient to mount two half-lenses in each rim, the upper half (convex or concave) of a power suited to the correction of the actual hypermetropia or myopia; the lower half, of the power needed for reading;* a similar effect is obtained, though somewhat less perfectly, by grinding the upper and lower halves of the same lens to different radii of curvature. Bifocal spectacles and eyeglasses, generally in rimless mounting, are also made by cementing a segment of a thin convex lens upon the back of the correcting glass required for distant vision, in such position that the wearer looks through it in reading. Still more elegant is a device by which a small and very strong convex lens, made of highly refracting glass, is embedded in the lower half of the glass required for distance; the entire glass is then ground to a uniform surface, so that the reading segment becomes practically invisible.† Another useful arrangement consists in mounting a supplementary reading correction in a separate frame, to be hooked upon the front of the spectacles habitually worn in distant vision.

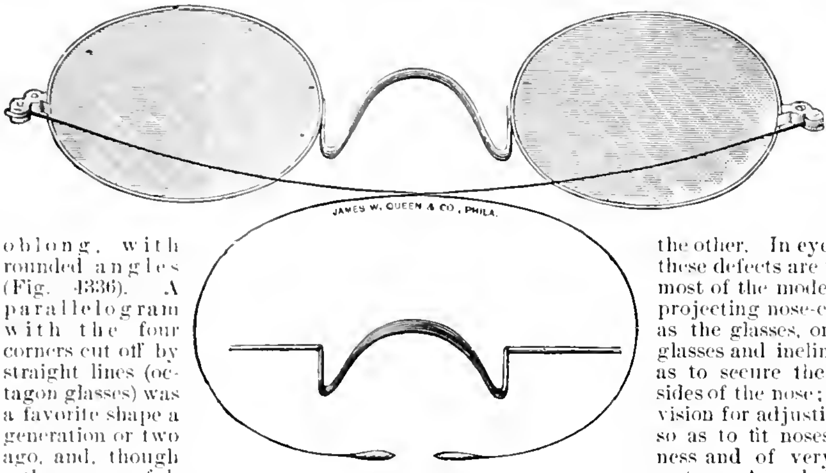

FIG. 4335.

Eyeglasses of the *pince-nez* ‡ pattern have been made since an early period in the history of spectacles, but their construction has been greatly improved within the past twenty years. In the older pattern (Fig. 4337) the centres of the glasses often fall much too near together, and the glasses themselves are apt to tip forward in a way that may be detrimental to their effect in distant vision. In many cases, also, they stand so near to the eyes as to allow insufficient room for the play of the eyelashes, and whenever the nose is unsymmetrical one glass is apt to stand noticeably higher or nearer to the eye than the other. In eyeglasses of improved construction these defects are to a great degree obviated. Thus most of the modern eyeglasses have some form of projecting nose-clips, set either in the same plane as the glasses, or in a plane behind that of the glasses and inclined to it at any required angle so as to secure the best possible bearing upon the sides of the nose; some eyeglasses have also a provision for adjusting the clips, upon the two sides, so as to fit noses of almost any shape and thickness and of very considerable degrees of asymmetry. A cork lining to the clips increases their adhesiveness, and so does away with the necessity of strong pressure in order to hold the glasses firmly in position. The tilting of the glasses, in cases of exceptional prominence of the forehead, is obviated by giving a forward slant to the connecting spring. For mounting cylindrical and prismatic glasses the *pince-nez* is generally unsuitable, by reason of the difficulty experienced in holding the glasses in proper position before the two eyes. In many cases of asthenopia, and especially in progressive myopia, the wearing of a *pince-nez* should be prohibited.

A convex lens, preferably of about four inches diameter and a focal length of about eight inches, with a handle by which it may be held at any desired distance from the book and from the eyes, is often used in reading by old persons with failing acuteness of vision. By reason of the greater distance of the glass from the eyes, its magnifying power is much greater than that of convex spectacles, and by varying the distance of the book the recti interni muscles are relieved of more or less of their load in convergence. A combination of two plano-convex

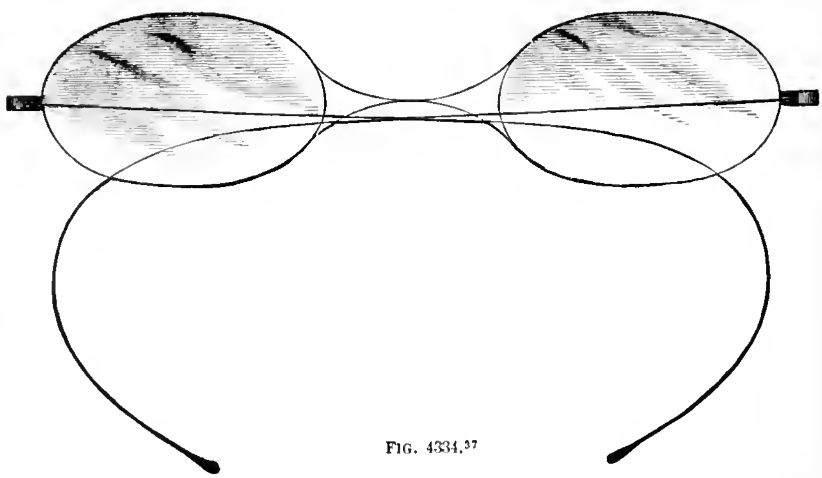

FIG. 4334.[37]

* Benjamin Franklin is said to have worn such glasses, and they are commonly called by his name.

† In this construction, and also in the more elaborate arrangement in which the correcting glass for distant vision is built up of two glasses cemented together (*cf.* Fig. 4324, *a d*), with the small reading lens enclosed in a cavity between them, there is an approach to an achromatic correction in the portion of the glass used in reading.

‡ In a fresco by Domº. Ghirlandajo (1449–94), in the Church of Sta. Trinita at Florence, an elderly bishop is represented as reading through a *pince-nez* set very low upon the nose; the rims of the glasses are circular, and the connecting arc is apparently rigid. This construction and manner of wearing the *pince-nez* recalls an objection formerly made to it, as compressing the nostrils and imparting a nasal quality to the voice. A fac-simile of the portion of the fresco containing this head has been reproduced, in color, in one of the publications of the Arundel Society, London, 1860.

lenses, mounted with their convex surfaces nearly but not quite in contact, is to be preferred to a double-convex lens, as giving a flatter field with less distortion of the virtual image.

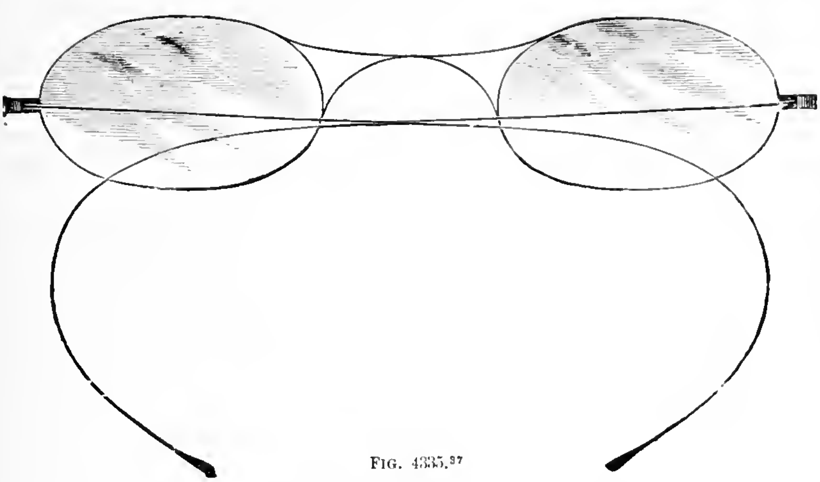

Fig. 4335.[97]

The different methods used in testing eyes for the correction of the several refractive and accommodative defects, whether simple or complicated, have been described in this Handbook under the titles *Astigmatism, Hypermetropia, Myopia, Presbyopia, Ophthalmometer, Ophthalmoscope, Optometry,* and *Shadow-Test.* The points to be particularly investigated are (1) the acuteness of vision, (2) the state of the refraction, (3) the state of the accommodation, and (4) the relation of the accommodation to the convergence. Only after these determinations have been made, with a close approximation to accuracy, can the selection of glasses for any particular kind of work be intelligently made. In the present state of diffusion of knowledge these tests can be safely intrusted only to the ophthalmic specialist — physicians and spectacle-dealers being alike incompetent, as a rule, to decide any but the simplest questions. A person who has arrived at the age of forty-five years without having experienced any trouble in the continuous use of his eyes, may fall into no very grave error in buying weak convex glasses when he becomes conscious that he is beginning to suffer from the disabilities of presbyopia; but even in such a case an examination of the eyes by a competent observer may bring to light some measure of astigmatism which it may be well worth while to correct, or possibly some pathological condition which it may be of vital importance to detect in its incipiency. The indiscriminate selling of concave spectacles and eye-glasses to young myopes, or to young persons hastily assumed to be myopic, is a most reprehensible, as it is, unfortunately, an almost universal practice.

The power of convex and concave spectacle lenses is expressed by numbers, with the plus (+) or the minus (−) sign prefixed. Two systems of numbering are in use, the older (inch) system, based on a unit-lens with two curved surfaces of equal radii of one Paris inch, and the newer (metric) system, in which a lens of a focal length of 1 metre (dioptric—D) is taken as the unit. In the older system it happens, through an accidental relation of the Paris to the English inch, that the focal length, in English inches, of a biconvex or biconcave lens is almost exactly the same as the radius of curvature of the two surfaces in Paris inches. The two systems may, therefore, be regarded as based upon unit lenses of one English inch and 1. metre focal length, respectively. The practical difference, in using the two systems, consists in the fact that in the case of the smaller unit, of 1. dioptric, the power of any lens of a power greater than this unit is expressed by a whole number or by a whole number and a decimal fraction, whereas in the case of the larger unit, of one English inch focal length, the power of any spectacle lens is expressed in the form of a vulgar fraction, with unity for its numerator, and the focal length of the lens, in English inches, for its denominator. The notation according to either system may, within a very small and practically negligible margin of error, be transformed into that of the other by taking the metre lens (dioptric) as equivalent to the lens numbered $\frac{1}{40}$ in the inch system.

Fig. 4336.[97]

Cylindrical lenses are numbered either according to their power (in dioptrics) or their focal length (in English inches) in the meridian at right angles to the axis.

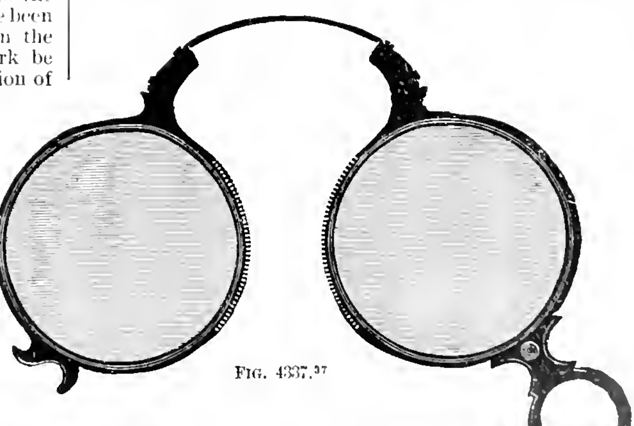

Fig. 4337.[97]

Lenses of unequal refraction in their two principal meridians are generally made by grinding a spherical and a cylindrical surface upon the two sides of the same glass, and the formula for such a lens is written, for each surface, as if the lens were made up of a plano spherical and a plano cylindrical lens with their plane surfaces in contact. The direction of the axis of a cylindrical lens or surface is defined by noting its inclination (in degrees of arc) to either the vertical or the horizontal meridian of the eye. If the two surfaces of any lens, at the points in which they are cut by the visual line, are not parallel, the deviation from parallelism is expressed by the magnitude of the angle which the two tangent planes make to each other, as if the two refracting surfaces were ground upon the two surfaces of a prism; the direction of the refracting angle of a prism is defined in the same manner as the direction of the axis of a cylindrical lens.

In prescribing spectacles it is convenient to lay off these angles on a printed diagram. Such diagrams have been in common use in this country since about 1876, and are furnished, in a variety of forms, by the opticians. In the diagram shown in Fig. 4338 the position is that in which the wearer is supposed to be looking through

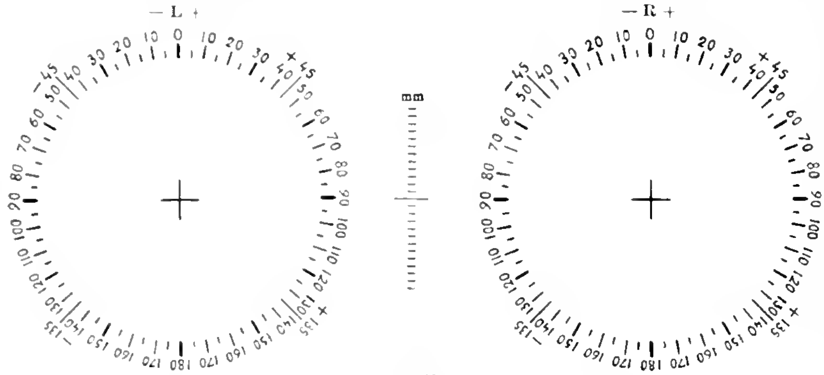

FIG. 4338.

his glasses, and the angles are marked, in degrees, with the plus (+) sign to the right, and the minus (—) sign to the left of zero, which is taken at the upper end of the vertical meridian. A widely used, but less natural, system of marking the angle of inclination is by beginning with zero on the horizontal line, at the left side, and numbering around the upper half of the circle to 180°. A half circle is sufficient to designate the direction of the axis of any cylindrical lens, but the whole circle of 360° is needed to indicate the different directions in which it may be required to turn the refracting edge of a prismatic glass.

The power of any (convex or concave) lens is measured by finding the equivalent (concave or convex) lens, and looking through the two lenses at a vertical line, such as a sash-bar of the window; the equivalence of the two lenses is shown by the absence of any enlargement or diminution of the virtual image, as indicated by the immobility of the image of the bar when the mutually neutralizing glasses are moved from side to side. In applying this test to a cylindrical lens the axis of the lens must be turned so as to coincide in direction with the line used as a test object; in the case of a sphericocylindrical lens the refraction is measured in the two principal meridians in succession, the algebraic difference of the two measurements representing the cylindrical refraction. The direction of the two principal meridians of a cylindrical or sphericocylindrical lens is found by holding the lens in a plane perpendicular to the visual axis, and looking through it at the sash-bar; the lens is then rotated, in its own plane, until the direction of the image coincides with that of the bar. This condition is fulfilled in two positions of the lens, at right angles to each other, in which positions the direction of one or the other principal meridian coincides with that of the bar. The middle point of any spherical or sphericocylindrical lens is found by noting the point at which the crossing of two sash-bars coincides in the image and in the object.

SPECTROSCOPY, MEDICAL.—The spectroscope is an instrument for examining the *spectrum*. A *spectrum* is, primarily, the series of colors produced when a ray of white light is transmitted through any transparent body, the surfaces of which are not parallel. The general form which this transparent body takes is that of an equilateral *prism* of glass, the sides forming an angle of sixty degrees. Hollow prisms with sides at the same angle are also used, being filled with transparent liquids.

Sir Isaac Newton first made the observation that when a ray of white light is transmitted through a prism the ray is not only bent out of its course, but is spread into an array of colors, the order of which is nearly invariable, no matter what the source of light or the material of which the prism is composed. Since the facility of differentiating colors varies in different persons, the exact tints of the spectrum so formed are not easy to express, but they are generally assumed to be seven in number, and arranged as follows: violet, indigo, blue, green, yellow, orange, red. If the ray of light be, as in Newton's original experiment, admitted through an opening of appreciable dimensions, the colors will be somewhat confused and will appear unbroken, but when the opening is very narrow a more distinct effect is produced, and, as will be seen below, the spectrum is crossed by numerous dark lines. It is a law of the propagation of light that when a ray passes from one transparent substance to another of different density it undergoes a deflection, known technically as *refraction*. The direction and extent of this refraction depend on the nature of the materials and on the difference of the densities. When the ray passes from a rarer to a denser subtance—for instance, from air to water, or from water to glass—the ray is bent (refracted) so as to be more nearly parallel to a line perpendicular to the surface of contact, while if the ray passes in the reverse direction—that is, from a denser to a rarer body, as from glass to water—the refraction is away from the perpendicular. It is upon this principle that the image-forming and magnifying properties of all lenses depend.

The accepted theories in regard to light refer it to very rapid vibration, and the difference between the various colors is supposed to be due to differences in the rate of vibration. White light is supposed to contain all the rates of vibration, and when such a ray undergoes refraction the different vibrations are refracted to different degrees, and hence are separated. If we view a ray through a plate of glass or other transparent body with parallel sides, the refraction produced in one direction on entering the glass is corrected by the refraction in the opposite direction on emerging, so that, with the exception of a slight displacement of the line of light, no striking optical change is manifest. If, however, the equilateral prism is used, the refraction on emergence is in the same direction as on entering, and the optical action is exaggerated. The separation of the different vibrations that compose a ray of white light is called *dispersion*, and is not coextensive with refraction; that is, bodies of equal refractive power do not necessarily separate the colors to the same extent. This law is a very important one in practical optics, for all lenses are forms with more or less prismatic outlines, and hence produce a dispersive effect. If it were only possible to prevent production of color by neutralizing the refraction, it would be impossible to construct any convenient optical apparatus free from colored images, but by combining different varieties of glass in such forms as to have equal and opposite dispersive powers with difference of refraction, large lenses entirely free from color defects (achromatic) may be constructed.

In the spectroscope the object is to secure as complete and extended a dispersion as possible; that is, to separate the colors thoroughly. For these purposes prisms of dense glass, or holl. w prisms filled with carbon disulphide, CS_2, are used.

The simplest method of examining the spectrum is to allow a ray of light to enter a dark room or dark box through a small opening and fall upon a prism. Upon the side of the room opposite the opening will be seen a more or less confused spectrum, in which all the colors will be found diverted from the path which the original ray would pursue if it did not enter the prism, the violet being most diverted and the red the least. Such a method of observation, however, is unsuitable for scientific purposes. The most serious defect in it is that if the ray has an appreciable thickness the vibrations on one part interfere and overlap those of the other, so that the series of colors obtained is really a combination of a number of spectra not coincident with each other. To obtain a pure spectrum the ray must be reduced to an exceedingly fine line of light, in which there will be but few sets of vibrations. This is accomplished by using a very narrow slit, and shutting off all light from the prism except that which passes through this slit. The observation is also much facilitated by viewing the spectrum through a telescope of low magnifying power.

About a century ago Dr. Wollaston, an English chemist, discovered, by using such a slit, that the spectrum of sunlight is not continuous, but is interrupted by numerous fine, dark lines. He did not develop this observation, and it was not until 1814 that Fraunhofer, a German optician, rediscovered these lines and mapped the positions of some of them. A few of the most prominent he distinguished by letters of the alphabet. They have in consequence generally been known as the Fraunhofer lines. They are all at right angles to the direction of the spectrum, and their distance from each other depends on the dispersive power of the prism. Since each particular line is always seen in the same color, and is more easy to define than the limits of the color itself, the lines are preferred for purposes of comparison.

Various improvements and advances in the construction of apparatus for observing spectra have been made from time to time, until the spectroscope in its usual form consists essentially as follows: A straight tube terminates at one end by a narrow, upright, adjustable slit, and at the other a convex lens, the focal length of which is the distance between it and the slit, so that the rays of light as they pass through the latter are rendered parallel by the lens. In the course of these rays is placed a dense glass prism, or series of prisms, greater dispersion being attained by a combination of prisms. A movable telescope of low magnifying power, arranged so that it can be brought in the course of the rays emerging from the prism, enables one to view conveniently the spectrum formed. Such an arrangement constitutes a *refraction spectroscope*. In the cut (Fig. 4339) there is shown a third tube, illuminated by a candle. This contains a graduated scale, an image of which is projected in the field of view above the spectrum, for the purpose of measurement, as given below.

Another form of the instrument depends on a somewhat different principle, and, as it is now in frequent use and possesses advantages over the older form, it will be necessary to describe it.

When the surface of a polished plate ruled with fine lines in close proximity is viewed obliquely, series of spectra are seen which are due to interferences in the different light waves as they are reflected from the angular surfaces produced by the ruling. This effect is called *diffraction*, and a plate so arranged is called a *diffraction grating*. The superiority of such an instrument rests principally on the fact that in all parts of the spectra the

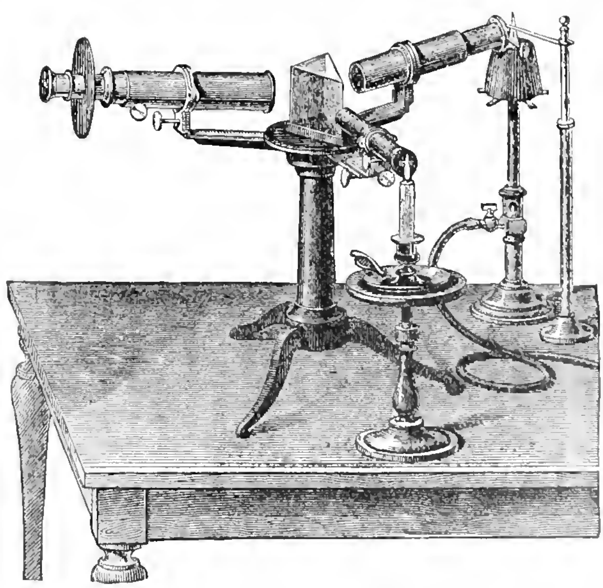

FIG. 4339.—Ordinary table spectroscope. In use the prism and abutting ends of the tube must be well covered to exclude light. This is usually attained by inserting them in the circumference of a brass box.

colors are proportionately distributed. In the ordinary spectrum, as seen by the prism, the dispersion is proportionately greater toward the violet end, and consequently this portion is abnormally spread out and the distances between the dark lines are exaggerated.

Spectra, by whatever method observed, may be divided into three groups:

1. Continuous spectra: those in which a more or less continuous sheet of color is seen, usually beginning with violet and ending with red. Such spectra are produced by the light which is emitted from solid objects in a highly heated state.

2. Interrupted or bright-line spectra: those in which the colors are seen in the form of narrow lines or bands, separated by proportionately wide, dark spaces. Such spectra are derived from light emitted by gaseous bodies in a highly heated condition.

3. Absorption spectra: those in which a nearly continuous series of colors is present, but interrupted by dark lines or bands. Such spectra are produced by various conditions, principally, however, by the transmission of white light, or light which would give a continuous spectrum, through substances which have the power of absorbing or annihilating special vibrations. In the applications of the spectroscope to medicine and organic chemistry these absorption spectra are the most important.

It is obvious from the above considerations that we have in the spectroscope, whether of the refraction or of the diffraction form, a very valuable means of studying structure. In the first place, we can determine with great exactness the character of the source of light, *i.e.*, whether it is composed of gaseous matter intensely heated or of solid particles. Further, taking a source of known character, we can, by interposing various substances in the path of the light, determine the effect which these substances produce upon the different forms of light vibrations present in the ray, and, as particular effects are often peculiar to particular bodies, we have here a means of identification. Thirdly, using a source of heat practically non-luminous, such as the flame of the Bunsen burner, we can detect different substances by the color which they impart to this flame, and when several such substances are present the eye alone is unable to separate and distinguish the colors, but by the spectroscope each tint is distinctly indicated.

As stated above, it is the absorption spectra that are most important in reference to the medical applications of the spectroscope. Except in the comparatively rare cases of the study of the character of light emitted by luminous organic bodies, living or dead, and in the detection of certain metals present in minute amount in the tissues and secretions, *e.g.* lithium, the direct study of normal spectra is not much resorted to in biological work.

The arrangement of the spectroscope for observation of absorption spectra is simple. An oil or gas flame is adjusted so as to throw a beam of light through the slit of the instrument, by which a continuous spectrum not broken at any point by dark lines is obtained. Sunlight does not answer so well for the purpose, because, owing to certain interfering conditions occurring at the surface of the sun, and also during the passage of the sunlight through our atmosphere, there are numerous absorption bands (Fraunhofer's lines) always present in its spectrum.

The material to be examined is placed in a cell with flat sides in the path of the light before it enters the slit. It is scarcely necessary to observe that to secure a satisfactory result the body must be sufficiently transparent to permit some light to pass through, otherwise no comparison as to the effect on different parts of the spectrum can be made. Such a condition is easily obtained by using solutions of the substance in the usual colorless solvents—water, alcohol, ether, glycerol, etc., and diluting until a satisfactory result is obtained. The character of the absorption spectra sometimes differs, according to the solvent used and the presence of free acid or alkali. Working spectroscopes are generally arranged so that two spectra can be compared, one being a standard obtained under known conditions, the other being that of the body to be tested.

To understand the functions of the spectroscope it is necessary to bear in mind that the colors seen are practically images of the slit through which the light passes, and that when the ray contains all the colors—that is, every vibration from violet to red—the prism, in setting out the vibrations according to dispersive power, gives, of course, a continuous series of images, that is to say, a continuous spectrum. When, however, in the ray of light that enters the slit any vibrations are missing, as in sunlight, or when by some interposed condition certain colors are struck out of the ray, the images which would otherwise be formed by those rays are missing, and hence the spectrum appears interrupted. When the interposed substance strikes out many rays, *e.g.*, deep-colored glasses, the great bulk of the spectrum is missing. The red glasses, for instance, used in photographic dark rooms strike out almost all rays but the red. The spectroscope as ordinarily constructed is, unfortunately, subject to serious defects, which can be avoided only by instruments of very expensive form. It has been found that all the forms of glass possess marked absorption powers for certain rays of light. If, instead of employing glass lenses and prisms, we use those made of quartz, and employ as a source of light the electric arc, or burning magnesium wire, a spectrum is obtained which is very much extended at the violet end. This portion of the spectrum exists to a greater or less extent in white light from any source, but is absorbed to such an extent by glass that it is not seen in the ordinary spectroscope. There are also color waves beyond the red, which are only demonstrable by special apparatus. In the usual applications of the spectroscope we cannot, therefore, utilize the so-called ultra-red and ultra-violet rays.

A very important advance has been made recently in practical spectroscopy in the application of photography. A sensitive plate is capable of responding to and recording conditions which the eye is unable to recognize, and we have, therefore, not only a method of extending our knowledge of spectra, but we may obtain permanent records of absolute accuracy, and independent of any general or special defects in vision. The photographic plate is especially capable of receiving impressions from the violet and ultra-violet portions of the spectrum, which are especially those which the eye appreciates with the greatest difficulty, while the yellow and red rays are practically inactive.

Many substances are known which have the power to retard the rate of vibration of light rays, so that they change the color of the light falling on them. Now the ultra-violet rays, which are inappreciable to the human eye, are caused by extremely rapid vibrations; any substance which will reduce this rate will bring the rays within the range of vision. This property is known as fluorescence. It does not come within the scope of this article to more than refer to it, but it may be mentioned that one of the best methods for the preparation of photographic plates is to incorporate into the sensitive material some fluorescent body by which the rays of light are modified and effects produced with colors that would otherwise be inactive.

The only way of acquiring familiarity with spectroscopic appearances is by actual use of the instrument. No drawing, colored or otherwise, can convey perfectly the appearances. Nevertheless, a method of indicating the character and position of the lines is useful, and several plans have been adopted. The use of colored plates is, of course, the most vivid, but too costly for most purposes. The usual methods are either by recording the position of any line, or the centre of a band, by its position on an arbitrary and fixed scale, or by angular position. A form of spectroscope made by Browning, of London, has this latter arrangement. The view telescope moves in a graduated arc, and cross-lines in the field enable it to be brought to exact position with any line. By such method or by the scale the lines may be mapped in their relative positions as seen in that particular instrument.

Another method is to indicate the positions of lines by their calculated wave lengths; that is, the length of one complete movement constituting the ray which produces a line at the given point. Such a method has the advantage of being an absolute indication, and not dependent on any particular instrument. Wave lengths are determined by mathematical calculation by means of the phenomena observed in diffraction, and the calculation may be easily applied to ordinary cases by plotting off on a chart certain lines of which the wave lengths are known, and interpolating those of which it is desired to determine the wave length. These lengths are very minute, and are usually expressed in millionths of a millimetre.

DESCRIPTION OF SPECIAL SPECTRA.—*Bright-line Spectra.*—Each of the known elements gives a special and distinct spectrum when heated sufficiently to become a luminous gas. It has been pointed out at the beginning of the article that solid substances give continuous spectra, and hence there is no appreciable difference between the spectroscopic appearances of the different elements as long as they remain solid bodies. When the temperature rises sufficiently to convert them into gases, and render them at the same time luminous, the characteristic bright-line spectra are obtained. This temperature can be attained with most elements only by the use of the electric spark. A few bodies, among which are potassium, sodium, lithium, barium, calcium, strontium, and boron compounds, yield, at the temperature of the non-luminous gas flame—Bunsen-burner flame—a limited number of rays which are early observed by the spectroscope as bright lines. Sodium imparts to flame a deep yellow color which consists of two tints, and is seen in the spectroscope as a narrow double line. Potassium gives red and violet lines. By increasing the temperature some of these spectra are modified. When the electric spark is employed the spectra obtained are usually more complex, the bright lines being numerous. The detection of the different elements by this means is not so widely applicable as might at first be supposed, for the method is extremely delicate, and it is difficult to distinguish between the minute traces which often have no significance and the presence of an appreciable amount. Nevertheless, the method has been of great usefulness in special cases in showing the occurrence of some elements in unexpected relations, and the wide distribution of others in minute quantities. Several elements, occurring in such minute quantities that ordinary chemical analysis would have failed to indicate them, have been discovered by the spectroscope.

There are a few substances which give a limited bright-line spectrum before reaching the temperature at which they became gaseous.

Absorption Spectra.—These are of several kinds. The absorption may affect a considerable part of one or both ends of the spectrum, by which a whole block of color may be cut out, or it may take place in broad bands or in fine lines. The spectrum of the sun and of many of the fixed stars is an example of the latter class. The lines of absorption are numerous, but they are narrow and represent but a small portion of the entire field, which appears to the unassisted eye to be a uniform sheet of color. Band absorption—that is, the cutting out of a considerable number of rays at some point on an otherwise continuous spectrum—is brought about very easily by means of many organic bodies.

Extended absorption, by which a considerable portion of the spectrum is absorbed, is seen in many substances possessing deep color, and the absorption may include all but a single color. Various colored glasses may be used. To test the effect of a graduated increase of color wedge-shaped glasses may be employed. Hollow wedge-shaped cells are often used for the examination of colored liquids.

The method of observing absorption spectra has been given above. It has been also already pointed out that no description, nor even drawing, can give an adequate idea of the actual appearances of spectra, but for the purpose of completing the article and indicating some of the practical applications of the methods a few absorption spectra will be described.

Line-absorption Spectra.—Some of the rarer elements possess the peculiar property, when in solution, of absorbing special rays of light. Among the best known of these are the metals formerly included under the term didymium. It consists of two elements, forming compounds that have distinct colors, but, even when so far diluted as to make the tint not perceptible, they give absorption bands. The vapors of bromine and of nitrogen dioxide, NO_2, which to the eye have much the same color, give each a peculiar series of numerous fine absorption lines in the central part of the spectrum. The absorption lines that normally occur in the spectra of the sun and stars are an important clue to the chemical composition and physical condition of those bodies, but a consideration of this topic does not belong here.

Band Absorption.—One of the most familiar and striking instances of this form of absorption is seen in *chlorophyl*, which is the general term under which the green coloring matter of plants is designated. A solution of this substance is easily obtained by macerating leaves with ether or alcohol. The filtered liquid being diluted so as to be fairly transparent, has a beautiful green color by transmitted light, and when viewed through the spectroscope transmits all the colors except a band in the extreme red, at which point there appears a well-marked broad dark band. The position of this band is highly characteristic of this substance, and can be detected by careful observation, even when the solution is too dilute to exhibit the color to the eye. In this way the adulteration of animal oils by vegetable oils—for instance, of lard oil by cotton-seed oil—may often be detected, for cotton-seed oil exhibits the absorption band of chlorophyl derived from the vegetable tissue.

Valuable use is made of absorption spectra in detecting the nature of various natural and artificial coloring matters. Fuchsin, for instance, not infrequently employed as an artificial coloring matter in wine, gives a broad but not very sharply marked band about the junction of the green and yellow of the spectrum.

It is, however, with reference to the absorption bands produced by the fluids of the animal body that the clinical applications of the spectroscope are seen. The most important of these are the appearances seen in blood under various conditions. These appearances are due to the hæmoglobin. As ordinarily seen by examining blood much diluted with water, the spectrum is that of oxidized hæmoglobin, *oxyhæmoglobin*. The dilution must be sufficient to allow considerable light to pass, and a modification of the absorption spectrum is obtained by continually adding water until no absorption at all occurs. The same effect may be produced by examining the solution through a wedge-shaped cell, gradually diminishing the thickness of the solution through which the light passes. The effects are briefly as follows: In rather strong solution, all the light is cut off except a portion of the orange and red; when the solution is diluted somewhat, green rays are transmitted, and the dark interval between these and the orange constitutes a broad absorption band; still further dilution produces a yellowish-green mass of light dividing the dark space into two nearly equal portions, developing, therefore, two well-marked absorption bands. On still further diluting, the absorption becomes reduced to a single band in the yellow. When to a solution of blood of sufficient density to give the two bands we add some reducing agent, *i.e.*, some body having an affinity for oxygen, the hæmoglobin is *reduced*, and a new spectrum is obtained. For this reduction ammonium sulphide is preferred. The spectrum of reduced hæmoglobin is a single band, broader than, and not exactly coincident with, either of the bands obtained from oxyhæmoglobin, the darkest portion corresponding to the mass of light dividing the two bands in that spectrum. The chemical condition of the blood in the vessels may in this way be tested. Another important result is in determining the effect of various gases and chemical substances in blood, either by direct action or by poisoning animals and quickly subjecting the blood to examination. If we examine blood charged with nitrous oxide (N_2O), we find the spectrum of reduced hæmoglobin, but agitating the blood with air will reproduce the oxyhæmoglobin. When, however, carbon monoxide (CO), carbonic oxide, is introduced into blood, we get a new condition which gives a spectrum resembling, but not identical with, that of oxyhæmoglobin, there being two bands, but their position being slightly nearer the violet.

Furthermore, we cannot so easily restore the original condition by agitating the blood with air, nor will the ordinary reducing agents produce the spectrum of reduced hæmoglobin. Carbon monoxide is known to be one of the most active of the gaseous narcotic poisons, and the above observations show, in part at least, the peculiar action it has on the essential breathing constituent of the blood. The carbon-monoxide-hæmoglobin spectrum is seen in the blood of persons poisoned by water-gas or fumes of burning charcoal, and an examination of the blood by the spectroscope in cases of this character may be an important medico legal point. Another important modification of the hæmoglobin is produced by the action of sulphides, especially by hydrogen sulphide (H_2S), sulphureted hydrogen. This gas is often present in sewer air, cesspool exhalations, and in other foul places, but not invariably, nor in so great quantity as is generally supposed. When its action upon blood is examined we find a spectrum which presents the broad single absorption band of reduced hæmoglobin (see above), but in addition a band in the red just at the junction with the orange. This band does not disappear on shaking the blood with air, although the two bands of oxyhæmoglobin appear. The body produced by the action of hydrogen sulphide on blood, and to which the properties above described are due, has been called *sulphæmoglobin*. It has been noticed that this substance cannot be formed by the action of hydrogen sulphide on reduced hæmoglobin, which is the form that exists in the veins; hence hydrogen sulphide may be introduced into the venous circulation without marked effect, but taken into the arterial system it is very dangerous. The difference between inhalations of this gas, by which it would get directly into arterialized blood, and its introduction into the system through the veins, has been shown strikingly in a method formerly in vogue of treating phthisis by injections of hydrogen sulphide and carbon dioxide. In this case the gas is taken up by the veins of the portal system and excreted before it comes in contact with the arterial blood.

If a solution of blood be exposed to the air for some time it undergoes various changes, accompanied by an alteration in the absorption spectrum. This alteration can be brought about by the action of weak acids, and also of potassium permanganate, on blood. A substance called *methæmoglobin* is formed. Its absorption bands are three, nearly coincident with those seen when sulphæmoglobin is shaken with air, but one band is more completely within the limits of the red. Methæmoglobin is believed to be a highly oxidized hæmoglobin, but its constitution is in some doubt.

Many other changes in the absorption spectra of blood are known, but while the investigation of them has much to do with physiological chemistry, the matter is too technical for discussion here. It is obvious, from what has been said, that very important medico-legal, toxicological, and even clinical questions can be determined by means of the spectroscopic appearances. The different effects produced on blood by different poisonous gases and vapors, the general symptomatology of which may be the same, offer a means of determining even post mortem the character of the gas.

Clinically, the spectroscopic appearances may be utilized for examining the fluids of the body either in their normal or in their abnormal condition. The spectrum of bile, for instance, may be utilized for the detection of it in the urine, for when the color reaction is too faint to be perceived by the unassisted eye, the spectroscope will show it. Normal urine contains a coloring matter believed to be derived from a constituent of bile, which gives a broad absorption band on the green. In certain febrile affections another band appears, also in the green, toward the border of the yellow. Blood in urine may also be detected by the spectroscopic tests. If it be in solution in the urine, the absorption spectrum is seen without difficulty. If the blood be present in the form of methæmoglobin, as is sometimes the case, it will give the three bands peculiar to that body, but it is necessary to distinguish these bands from those produced by a decomposition product of hæmoglobin known as *acid hæmatin*. This distinction can be made by the use of ammonium sulphide, when, if methæmoglobin is present, the band of reduced hæmoglobin, as described above, will appear. If the blood is in the insoluble form no absorption bands may be shown. In this case the blood is filtered and the filter paper treated with alcohol and ammonia, and then with ammonium sulphide; bands then appear which are due to *reduced hæmatin* formed by decomposition.

In the accompanying map (Fig. 4340) are shown some of the important absorption spectra as seen in a refraction

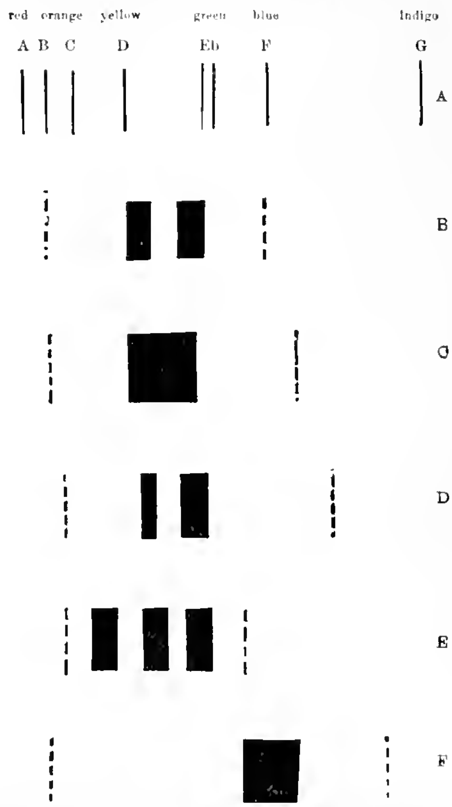

FIG. 4340.—A. Principal lines of solar spectrum as seen in a refraction spectroscope. B. Absorption bands of oxyhæmoglobin. C. Bands of reduced hæmoglobin. D. Bands of carbon monoxide hæmoglobin. E. Bands of methæmoglobin. F. Spectrum of normal urine.

spectroscope of moderate power. Over the plate has been placed indications of the limits of the various colors, but these must be regarded as a mere approximation, as it is not possible to determine precisely at what point one color ceases and another begins. The dotted lines at each end of the plates represent the limits of the visible spectrum in each case, and it will be noticed that there is considerable extinction of color, especially toward the violet end. *A* represents the spectrum of sunlight, with some of the principal absorption bands, and the letters which distinguish them. All these bands, as has been remarked above, are absent in the light of ordinary flames and electric lights. The observation of absorption spectra being made with artificial light does not therefore show any such bands. *B* shows the absorption bands of oxyhæmoglobin. The visible spectrum, it will be seen, extends only from green to a short distance on the red. *C* shows the spectrum of reduced hæmoglobin. The limits of the visible spectrum are extended slightly toward the violet. *D* is the spectrum of carbon monoxide hæmoglobin, that is, of blood impregnated with carbon monoxide. *E* is the spectrum of methæmoglobin. *F* is the spectrum seen commonly in normal urine. The broad band is at about the junction of the blue and green and is somewhat faint.

Limited practical clinical application is made of these spectroscopic appearances. The instruments required are expensive and involve delicate adjustment, and hence they are unsuited to the general uses of the practitioner. A combination of spectroscope and polariscope has been constructed for use in rapid approximate estimation of sugar in urine. The use of the spectroscope in the detection of various natural and artificial colors, and in the recognition of blood stains, belongs to special treatises.

Henry Leffmann.

SPERMACETI.—(*Cetaceum*, U. S. P., B. P.; Ger., *Blanc de Baleine ou Cétine*; Cod. Med., *Sperma-Ceti*). A solid paraffin-like substance obtained from cavities in the head of the sperm-whale, *Physeter macrocephalus* L. (order *Cetacea*). This whale is the largest living animal, gregarious in its habits and found in the oceans of both hemispheres, from the extreme north to the tropics. It is hunted for its oil, which is one of the most valuable of its class.

Crude spermaceti is a semisolid, yellow substance as it is scooped out from its reservoirs, but becomes hard and brittle upon exposure to cold; for purification, it is then pressed in bags, when the oil squeezes through, and the solid *cetaceum* is left behind. This can be further purified by melting in water, skimming, and recrystallization. Purified spermaceti is a pearly white, glistening, crystalline, translucent, odorless, and tasteless solid, insoluble in water; soluble in ether, chloroform, and boiling alcohol. Melting point 111° to 112° F. It is mostly composed of *palmitic* acid combined with *cetyl* (instead of glycerin); there are also small quantities of compounds of *stearic*, *myristic*, and *lauric acids*. It is fairly permanent in the atmosphere, in this respect excelling most fats.

Use.—Spermaceti has no active medicinal qualities. It is sometimes used in sore throats, etc., where its value is mostly as a protective. Its principal employment in medicine is as an ingredient of cerates and ointments, to which it gives consistence, blandness, and permanence.

There is an official cerate (*Ceratum Cetacei*) consisting of 35 parts of white wax, 10 of spermaceti, and 55 of olive oil, made by melting together the two former, adding the oil, previously heated, and stirring constantly until cold. Spermaceti is also an important constituent of ointment of rose water or cold cream (*Unguentum Aquæ Rosæ*, U. S. P.). *W. P. Bolles.*

SPERMATORRHŒA. See *Sexual Organs, Male, Diseases of.*

SPERMATOZOA.—(Greek, σπέρμα, seed, and ζῶον, an animal.) A *spermatozoon* is a free, usually motile cell that is capable of uniting with an ovum to form the germ of a multicellular organism. The penetration of the ovum by the spermatozoon and the union of the nuclei of the two cells constitute the chief processes in the act of fertilization, which is the essential feature in sexual reproduction; and the ability to produce spermatozoa or their equivalent is the essential distinction of organisms of the male sex (see *Sex*). The spermatozoon is distinguished from the ovum by being vastly smaller and generally by being capable of locomotion (see *Ovum*).

Historical.—Spermatozoa were observed for the first time by Ludwig Ham, a pupil of Leeuwenhoeck, who in turn communicated the discovery to the Royal Society of London in a letter dated November, 1677. The discovery of these minute living bodies in the semen of man and a number of animals aroused great interest, especially as Malpighi a few years before (1672) had published the results of his observations on the embryology of the chick, and had concluded, in contradiction to Harvey, that the embryo is preformed in the egg. Now the question arose as to whether the moving elements of the semen might be germs which enter the eggs and develop into embryos. Leeuwenhoeck took the affirmative position and had many followers, but a greater number of the preformationists took the opposite view and held those bodies to be merely internal parasites. The name "spermatozoa" was given to them by von Baer with this idea in mind. The position of the "ovists" was strengthened by Bonnet's discovery of parthenogenesis, published in 1762 (the experiments were begun in 1740), which showed that in some cases an embryo can be formed without a male parent.

The first successful step toward a real knowledge of spermatozoa by means of experiments in artificial fertilization of ova of animals was made by Jacobi, and communicated to the Berlin Academy by Gleditsch in 1764. Jacobi placed the ripe spawn of salmon and trout in water and added seminal fluid squeezed from a male. After five weeks the eggs showed signs of life. It was apparently not these experiments, however, but some unsuccessful attempts made by Malpighi much earlier that led to the truly remarkable series of experiments by Spallanzani (1786). He wisely chose the amphibia for his material. First, he showed that eggs taken from the oviduct could be caused to develop by the addition of sperm taken from the seminal vesicles, while similar eggs not so treated failed to develop.

Second, he disproved the idea current at that time that the fertilizing element was an *aura seminalis*, a seminal vapor. This was done by causing frog's eggs to adhere to a watch glass, which was then inverted over another containing some of the sperm, and both were put in a warm place. The eggs became wet by the condensation of the vapor that was distilled from the sperm, but no fertilization took place. After some of the material in the lower watch glass had been added to the eggs, however, they speedily developed.

Third, by filtering the sperm he showed that the *liquor seminalis* has no fertilizing effect, but that the residue washed from the filter paper has undiminished power. Spallanzani was prevented from reaching correct conclusions as to the nature of the spermatozoa, however, because he accepted Bonnet and Haller's theory of the preformation of the germ in the female, the truth of which he thought he had demonstrated in the amphibia. Spallanzani produced artificial fertilization also in the eggs of silk moths and in a dog.

The next important contribution to the history of the spermatozoa is furnished by the brilliant observations and experiments of Prévost and Dumas (1824). They studied the anatomy and secretions of the reproductive organs of vertebrates of all classes above the fishes, and found that spermatozoa are produced in the testes only, and that these are the only organs essential to the fertility of the male; that spermatozoa exist in all fertile males and are absent from immature and senile individuals and from infertile hybrids; and that each species has its own peculiar form of spermatozoon. Having thus shown the close relation between the spermatozoon and its host and the correlation between the presence of spermatozoa and fertility of the male, these authors proceeded to repeat Spallanzani's experiments upon frog's eggs. They made improvements upon his methods, making the experiments more exact, and they demonstrated further that the spermatozoa are capable of penetrating the jelly surrounding the eggs. Spallanzani's results in regard to the aura seminalis and the liquor seminalis were confirmed and the important conclusion added that the spermatozoa are the essential fertilizing elements.

After all this it seems very strange to find the spermatozoa included in Owen's article on "Entozoa" in

"Todd's Cyclopædia" (vol. ii., 1836–39), and to read in Johannes Müller's "Physiology" (1840) that it is doubtful whether the spermatozoa are parasites or living parts of the animal in which they occur.

This uncertainty is due to the fact that the observations recorded heretofore lacked two essential points: they failed to show how the spermatozoa arise in the testis, and they failed to give any hint as to how the spermatozoa behave upon reaching the ovum. The first of these gaps was filled by a series of papers by Kölliker beginning in 1841, in which, besides describing the spermatozoa of a large number of species, largely invertebrate, he shows that they arise by the metamorphosis of cells in the tubules of the testis.

Although, according to J. A. Thomson, the union of spermatozoon and ovum was observed in the rabbit by Martin Barry, an Edinburgh medical student, in 1843, it really remained for

O. Hertwig to fill the second gap many years later (1875) from observations on starfish eggs. In this favorable material he was able to demonstrate that fertilization is effected by the entrance of one spermatozoon into the egg and the union of its nucleus with the egg nucleus. Thus two centuries, less two years, elapsed between the discovery of spermatozoa and the demonstration of the part played by them in the important function of reproduction. Even then the knowledge gained was very superficial. Much has been done during the past quarter-century toward gaining a deeper insight into the nature of the spermatozoon and the process of fertilization, but there is still an inner mystery into which our minds and our microscopes are equally unable to penetrate; and, while we may expect great progress in the future, it is probable that there will always be a limit beyond which the man of science must say, "I do not know" (see *Impregnation*).

Morphology.—There are as many forms of spermatozoa as there are species of animals. We may take as our type the spermatozoon of man, because of its intrinsic interest as well as on account of its relatively simple structure (Fig. 4341).

In the spermatozoa of vertebrates Waldeyer distinguishes three regions—the head, the neck, and the tail. The head of the human spermatozoon is flattened. The wider face is broadly oval or nearly elliptical (Fig. 4341, *A*). Viewed from the side, it is seen to be more flattened toward the apex, the proximal two-thirds being narrowly ovate (Fig. 4341, *B*). According to Meves, the head may be divided into two parts—anterior and posterior (*P.a.* and *P.p.*, Fig. 4342). The anterior part is covered with a thin protoplasmic cap extending to the line *L.Gal.*, Fig. 4342, *B*. From its staining reactions and its history the head, with the exception of the cap and a thin covering membrane, is known to be composed of the cell nucleus with its chromatin contents. The neck of the human spermatozoon is inconspicuous (*Cl.*, Fig. 4342). It is in all forms a short region joining the head and tail, and containing the anterior centrosome (*Nd.a.*, Fig. 4342, *B*) and the homogeneous material connecting it with the posterior centrosome (*Nd.p.*). The tail (*Cd.*, Fig. 4342) contains three parts—the middle piece, the principal part, and the end piece (*P.c.*, *P.pr.*, and *P.t.*, Fig. 4342, *A*). Throughout the length of the tail there extends an axial filament, which has been shown by maceration to be a bundle of extremely minute fibrils. The middle piece is about as long as the head and, according to Meves, has a rather remarkable structure. At its extremities are the two parts of the outer centrosome. The axial filament has its origin in the anterior part (*Nd.p.*, Fig. 4342) and passes through the posterior part, or annulus (*Ann.*, Fig. 4342). The axial filament is surrounded by an inner sheath. Outside of this is a spiral fibre lying in a clear substance. This is covered by a finely granular protoplasmic layer, the mitochondria. The principal part of the tail consists of the axial filament and a covering, the involucrum, which is probably continuous with the inner sheath of the middle piece. The end piece consists of axial filament alone.

Human spermatozoa are small compared to those of some other mammals, as will be seen by reference to the following table made from data given by Boston (1901):

SPERMATOZOA OF	Total length.*	Head.		Tail length.
		Length.	Width.	
Man	51–58	4–6	3–4	41–53
Dog (mastiff)	67–74	4–8	3–4	59–67
Rabbit	51–66	6–9	3–4	45–58
Horse	64–67	6–8	3–4	51–60
Bull	87–93	9	6	77–83
Sheep	83	9	6	74
Cat	58–74	6–7	3–5	53–66
Mouse	120–158	8–9	3–4	112–138
White rat	225–238	12–16	......	209–222
Guinea-pig	113–138	6–12	7–11	102–132

* All measurements are given in thousandths of a millimetre (μ).

Some of these figures differ considerably from those given by Waldeyer (1902, pp. 158, 159), and this is probably due to there being a large amount of individual variation among the spermatozoa from a single subject as well as variation in the types of spermatozoa produced by different males of the same species. Among the vertebrates the smallest spermatozoa are found in Amphioxus, 16 to 21 μ in length according to Sobotta, while the largest are produced by a European toad, *Discoglossus pictus*, the length, according to Spengel's measurements, being 2,000 μ = 2 mm.

The various forms of spermatozoa are classified by Waldeyer into two principal groups and several subdivisions as follows:

I. Spherospermia.
  1. Without appendages.
  2. With appendages.
II. Nematospermia.
  1. Without lateral membrane.
    (*a*) Head rounded.
    (*b*) Head elongated.
  2. With lateral membrane.
    (*a*) Head rounded.
    (*b*) Head elongated.

To the first group, spherospermia without appendages, belong the simple spermatozoa of the nematoda. For example, Ascaris has a simple conical spermatozoon without appendages of any kind.

Spherospermia with appendages are characteristic of the decapod crustacea—the lobsters, crabs, and their allies. They present a great variety of form. There is generally a more or less rounded body with several or many spine-like projections.

The human spermatozoa belong to the group of nematospermia without lateral membrane and with rounded head. These have been sufficiently described above. In the simple spermatozoa of a medusa, Aurelia, we find an elongated head tipped with a sharp point, or *acrosome*. In some of the more complicated spermatozoa the head is very much elongated and the long sharp acrosome is provided with a barb like a minute harpoon. The lateral membrane is a fin-like fold lying on one side of the tail and it usually shows undulating movements. At its margin it encloses a fibre made up of fibrillæ, like the axial fibre. This form of spermatozoa is especially characteristic of the tailed amphibia.

Besides the normal spermatozoa there have been found in many species abnormal forms—giant spermatozoa, worm-like, double ones, etc. Some of these forms are clearly pathological, but in other cases there may be a normal dimorphism.

Early Development.—The course of development of spermatozoa is identical with that of the ova up to the time of the differentiation of the gonads (see *Ovum* and *Reduction Division*).

Confining our attention for the present to the vertebrates—the rudiment of the testis, like that of the ovary, is a genital ridge lying upon the Wolffian body, and continuous with the peritoneum of the upper part of the body cavity. The seminiferous tubules are formed from strands of cells that grow into the stroma from the thickened epithelium of the genital ridge. According to B. M. Allen, these strands are homologous with the medullary cords of the ovary (see *Ovum*). They subsequently acquire a lumen, and become connected with the rete tubules, which in turn connect with the vas deferens.

The young seminiferous tubules contain two kinds of cells—large, clear, spherical germ-cells, or *archispermiocytes*, with large, round, darkly staining nucleus; and between them *epithelial cells*.

There is no further change until the advent of sexual maturity; then the process of spermatogenesis begins (Fig. 4344.) The archispermiocytes divide, one daughter cell of each pair remaining deep in the epithelium as a reserve germ cell (*spg. r.*, Fig. 4345), while the other changes somewhat in appearance and becomes a *spermatogonium*. The spermatogonia divide a number of times (*spgm.*, Fig. 4345) and finally produce a generation of *primary spermatocytes* (*spc.a*, Fig. 4345). These pass through the characteristic stages of synapsis and growth (*spc.g.* and *spc.i.*, Figs. 4346 and 4347). Finally, each

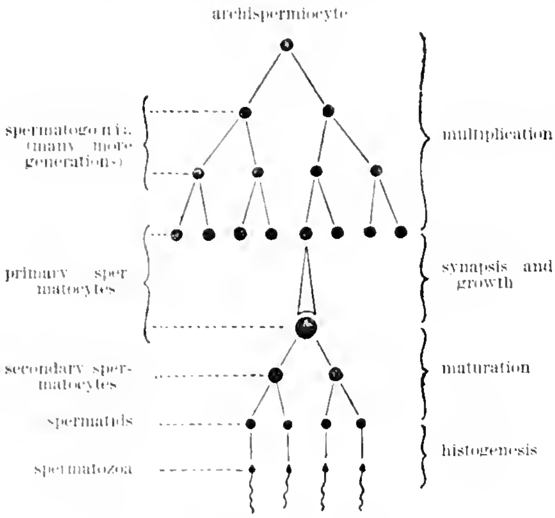

FIG. 4344.—Diagram showing the Genesis of the Spermatozoa. (Modified from Boveri.)

primary spermatocyte divides to form two secondary spermatocytes, and each of these in turn divides, giving rise to two spermatids (*spd*, Fig. 4345). During the divisions the process of maturation takes place (see *Reduction Division*).

In the mean time the epithelial cells have been undergoing a transformation into the peculiar "*cellule ramificate*" first observed by Sertoli in 1865. The cytoplasm of these cells is naked and extends in amœboid fashion among the germ-cells toward the lumen of the tubule. After the last maturation division the spermatids (*spd*, Fig. 4345) become united with the protoplasmic processes of the Sertoli cells (*symphoresis*, Waldeyer), and remain in this connection throughout the period of histogenesis. When the spermatozoa are fully developed they are released, and the Sertoli cell becomes connected with a new set of spermatids (Fig. 4345).

This peculiar condition in the vertebrate testis has caused much confusion in the past and has led to erroneous theories as to the nature of the spermatozoa. Although Sertoli regarded the cells which bear his name as nutritive cells, von Ebner in 1871 called them "spermatoblasts" and regarded them as directly concerned in the production of spermatozoa. In this view von Ebner had many followers. The correct theory was advanced by H. H. Brown in 1885 and by Benda in 1887, and in 1888 von Ebner corrected his error and added much to the knowledge of the Sertoli cells.

Another cause of confusion in the study of spermatogenesis in the vertebrates is that before one cycle of development is completed in any part of a seminiferous tubule another begins. In the bull the spermatogenesis is a continuous process and in sections of the testis of an adult individual four stages will be found in the wall of each tubule (Figs. 4345 to 4347), but in order to follow the consecutive stages a number of sections must be examined.

The nuclear changes leading to the formation of the spermatids have been described sufficiently in another article (*Reduction Division*), and we will pass directly to the consideration of the process by which the spermatid becomes a spermatozoon, confining our attention entirely to the vertebrates and making the description as general as possible.

Histogenesis.—After the division of the secondary spermatocyte the nucleus of the young spermatid acquires a nuclear membrane and passes into the resting condition with a chromatin reticulum. The centrosome moves from its original position and divides into two, either completely or incompletely, forming a minute dumb-bell-shaped structure. In its new position the outer part lies close against the cell wall, while the inner part is directed toward the nucleus. The "sphere" of denser protoplasm that collects around the centrosome after earlier cell divisions now forms independently of the centrosomes and is called the *idiosome* (*s*, Fig. 4348).

The fate of the various parts of the cell in the development of the spermatozoon is summarized by Waldeyer as follows: Out of the chromatin of the nucleus is developed the head of the spermatozoon; a part of the idiosome forms the acrosome; the centrosome takes part in the formation of the neck, the middle piece, and the axial filament; the cytoplasm gives rise chiefly to the axial filament, its mitochondria forms the spiral structures, and it takes part in the formation of the envelope of the tail.

The nucleus first moves from its originally central

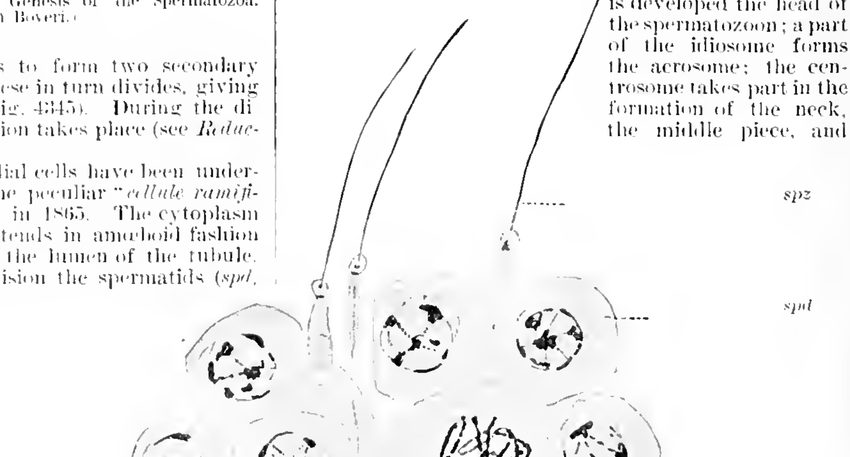

FIG. 4345. Part of Section of Testis of a Bull, showing Stages in Spermatogenesis. *c.s.*, Sertoli cell; *spg.r.*, reserve spermatogonium; *spg.m*, spermatogonia in mitosis; *spc.a.*, first stage in development of spermatocyte; *spc.i*, spermatocyte in later stage; *spd*, newly formed spermatid just after the last maturation division; *spz*, nearly ripe spermatozoon, separated from Sertoli cell. Highly magnified. (After Schoenfeld.)

position to the periphery of the cell opposite the centrosomes. Its chromatin network becomes gradually finer and more condensed until it forms an apparently homogeneous mass; at the same time the nucleus becomes smaller and gradually assumes its definitive shape.

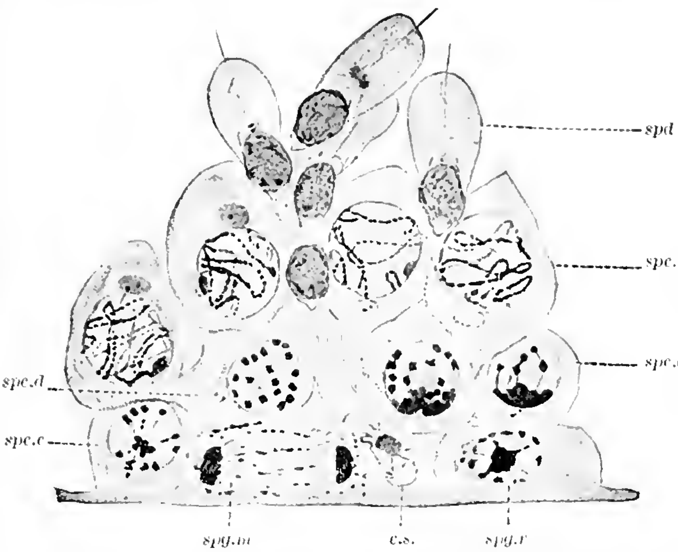

FIG. 4346.—Another Section of the Testis of a Bull. *spg.m*, Reserve spermatogonium in mitosis; *spc.c*, *d*, and *e*, spermatocytes in stages preliminary to synapsis; *spc. i*, advanced primary spermatocyte, growth nearly completed; *spd*, spermatid attached to Sertoli cell (*c.s.*) and undergoing histogenesis. Highly magnified. (After Schoenfeld.)

In the mean time a part of the idiosome, often containing a vacuole, becomes attached to the nuclear membrane and moves around the nucleus to take its position at the apex and becomes the acrosome (Figs. 4348 and 4350).

The outer centrosome becomes disc-shaped, and at a very early stage there grows out from the centre of the disc, or in close connection with it, a very fine filament, the rudiment of the axial filament of the tail (*ax*, Fig. 4348). The development of the tail, as remarked by von Ebner, is one of the most difficult problems of histogenesis. It is described variously by different authors for the same or closely related forms, and the course of development appears to differ considerably in the two groups of vertebrates in which it has been most carefully studied—the amphibia and the mammals. All agree, however, that very soon the periphery of the outer centrosome becomes separated from the axial filament and forms a ring surrounding it. In the amphibia (Fig. 4350) the axial filament appears to remain connected with the inner centrosome, while in the mammalia (Fig. 4348) the inner centrosome is free and the central part of the outer centrosome forms the end knob of the axial filament. In the mean time the whole apparatus has been moving toward the nucleus. The inner centrosome becomes attached to the nucleus and marks the position of the future neck. The central part of the outer centrosome with the axial filament follows, but in the mammals does not quite reach the same point, while the ring remains at or near the cell wall. The axial filament has been growing meanwhile and now consists of two parts, one within the cell and the other outside. The intracellular part will form the axis of the middle piece, and the outer part, the axis of the main part and the end piece of the tail. The material for the growth of the filament is probably furnished by the cytoplasm. The fate of the ring centrosome differs in the two groups. In the mammalia it remains intact and becomes the annulus at the distal end of the middle piece (Fig. 4349). In the amphibia part of it stretches out along the axial filament and gives rise in connection with the cytoplasm to the envelope of the main part of the tail. In the mammalia this part of the tail appears to be formed by differentiation of the surface of the axial filament.

As the spermatozoon begins to take shape the main part of the cytoplasm draws backward, leaving only a thin membrane on the head, and the mass of cytoplasm lies in the position of the middle piece (*cy*, Fig. 4349). Scattered thickly through the cytoplasm are fine granules with charcteristic staining qualities, the mitochondria, supposed to have been furnished by the Sertoli cell. The spiral filament is formed by the concentration and fusion of this material.

In the mammalia and some other forms there is more cytoplasm than can be used in the development of the spermatozoon. This part begins to undergo degenerative changes, and at the same time is gradually constricted off from the middle piece (*cy*, Fig. 4349 *F*). The cytoplasmic remnants may remain attached to the Sertoli cell for a time after the spermatozoa have moved away.

After leaving the testis the spermatozoa undergo a further "ripen-

ing" process, which consists chiefly in the completion of the outer envelope of the middle piece and the smoothing off of any projections or irregularities that may have remained after separation from the Sertoli cells.

It will be seen from this brief review of the development of spermatozoa that there can be no further question as to the character of these bodies. Each one contains all the essential elements of a cell.

SPHYGMOGRAPHY.—Sphygmography (Gr., σφυγμός, the pulse; γράφειν, to write), strictly interpreted, is the art of taking pulse tracings. The present article will deal not only with the art of recording the arterial and the venous pulse, but also with the graphic method as

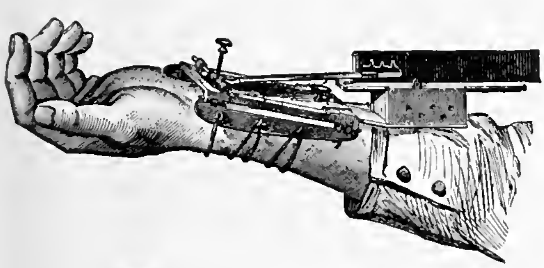

FIG. 4351.—Marey's Sphygmograph (new form).

applied to the heart (cardiography). The instruments employed for these purposes are of many types, but the principles involved can be made sufficiently clear by a few examples. Two essentials are common to all of them, a recording surface and a writing lever or pen. The recording surface is usually smoked paper set in motion by clock-work. The writing lever may be directly applied to the pulse or connected with it by a rigid or jointed support, in which case we speak of *direct sphygmography;* or the move-

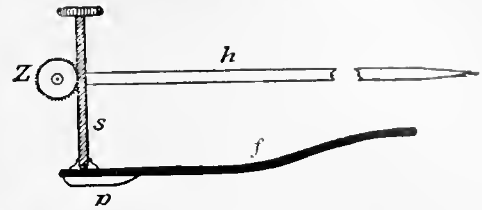

FIG. 4352.—Diagram of Connections in Marey's Sphygmograph.

ments to be recorded may be carried to the lever by air transmission, constituting *indirect sphygmography.*

DIRECT SPHYGMOGRAPHY.—Two examples of direct sphygmography will be given as represented in the instruments of Marey and of Dudgeon.

In *Marey's sphygmograph* (Figs. 4351 and 4352) the button *p* is pressed down upon the artery by the spring *f*. The screw *s* is connected with the button by a joint and rests against a cog-wheel *Z*, which is on the axis of the writing lever *h*. The thread of the screw catches in the teeth of the cog-wheel so that when the button is lifted by the pulse it raises the screw so as to turn the wheel and elevate the lever. At one end of the instrument there is a clock-work which moves a metal frame carrying a strip of smoked paper. The screw, which may be seen in Fig. 4351 under the centre of the writing lever, regulates the pressure of the button on the pulse.

In using the instrument, a strip of smooth paper is cut to fit the frame and smoked over a piece of burning camphor, a lamp burning without a chimney, or a tallow candle. The position of the

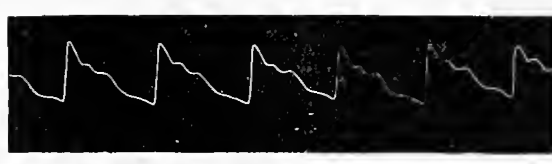

FIG. 4353.—Sphygmogram taken with Marey's Sphygmograph.

radial artery is determined and the point where the pulsation is best felt is noted. The instrument is then

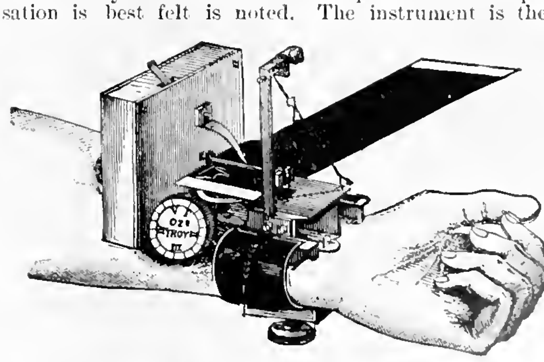

FIG. 4354.—Dudgeon's Sphygmograph.

bound to the arm, as shown in the figure, with the button on the point selected. The clock-work is wound up. The pressure of the button is regulated by the screw provided for the purpose, so that a suitable excursion of the lever is obtained with each pulse. It is usually wise to be satisfied with a moderate excursion of the lever, as with a maximum movement there is more inertia and the tracing may not represent the actual pulse so accurately. The lever can be brought to write at a proper level on the paper by turning the screw *s*. Care must be taken that the writing point of the lever is in contact with the paper but not pressing too heavily.

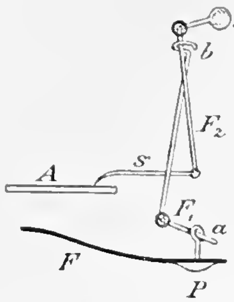

FIG. 4355.—Diagram of Connections in Dudgeon's Sphygmograph.

If the hand is steady and everything seems right, the clock-work may now be set in motion and the tracing taken. The tracing is removed from the frame and anything desired, such as the patient's name, the date, and the pulse rate, scratched upon it with a pin or other sharp instrument. Finally, it is to be fixed by dipping it in a suitable varnish. The writer uses a solution of shellac in methylated spirits with a little glycerin added to prevent the tracing being too brittle. Others use negative varnish, such as is employed by photographers, and yet others friars' balsam. A sample of the result obtained with Marey's sphygmograph is shown in Fig. 4353. For the interpretation, see the article on *Pulse*.

Dudgeon's sphygmograph (Fig. 4354) has the advantage over Marey's of being more compact and having a simpler arrangement for connecting the smoked paper with

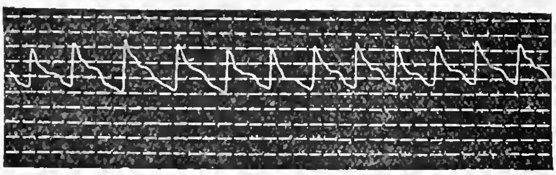

FIG. 4356. Sphygmogram taken with Richardson's Sphygmograph.

the clock-work. The arrangement of the levers is shown in Fig. 4355. This instrument is applied to the wrist in much the same way as Marey's. The pressure of the button on the pulse is regulated partly by the tightness of the band around the wrist, and partly by turning the wheel marked *oz troy*, which regulates the pressure of the spring.

Richardson's sphygmograph is a modification of Dudgeon's, which is preferred to it by some. In Richardson's modification the pressure is regulated by a movable weight, and the rollers which move the paper are supplied with teeth which mark broken horizontal lines upon the tracing. An example of a tracing taken with Richardson's sphygmograph is shown in Fig. 4356. Dudgeon's sphygmograph is the one to which the writer is most accustomed, and he finds it very satisfactory. It is compact, simple, and moderate-priced.

In the more elaborate sphygmographs of von Jacquet and of Frey there are arrangements for recording the time, and von Jacquet's permits of varying the rate at which the paper moves. There are often more disadvantages than advantages, however, in having too complicated an instrument.

INDIRECT SPHYGMOGRAPHY.—This is where the pulse is brought to bear upon a writing lever some distance away by transmission

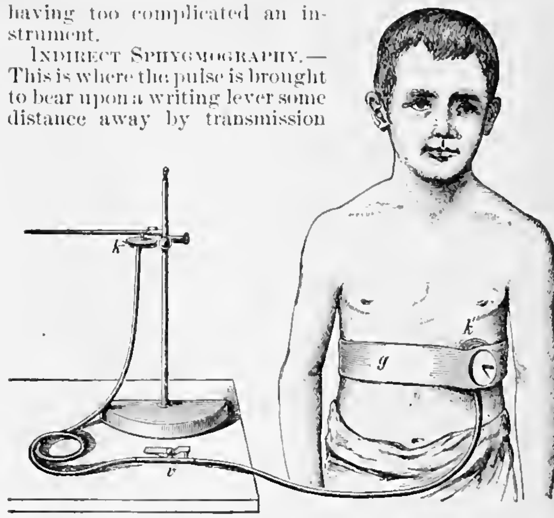

FIG. 4357.—The Cardiograph Applied.

of the changes in pressure through a rubber tube. By this method events occurring at different parts of the body may be made to record themselves one under the other on the same paper. It is well adapted for obtaining tracings of the cardiac impulse and of the carotid and jugular pulses.

For the recording surface a kymograph is required. This is the principal disadvantage of the method, for kymographs are usually large and not very portable. The arrangement of the apparatus for receiving and transmitting the cardiac impulse is shown in Fig. 4357. The essential parts of the apparatus are a receiving tambour, a connecting tube, and a recording tambour. A receiving tambour for the cardiac impulse is known as a *cardiograph*, and an example is shown in Fig. 4358. *k* is a shallow metal box or tambour covered with rubber membrane and bearing a button, *p*, to press

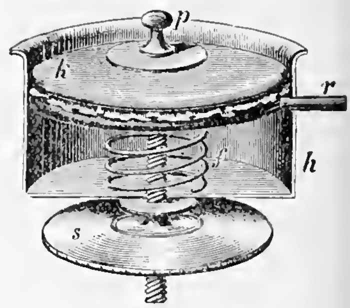

FIG. 4358.—Marey's Cardiograph.

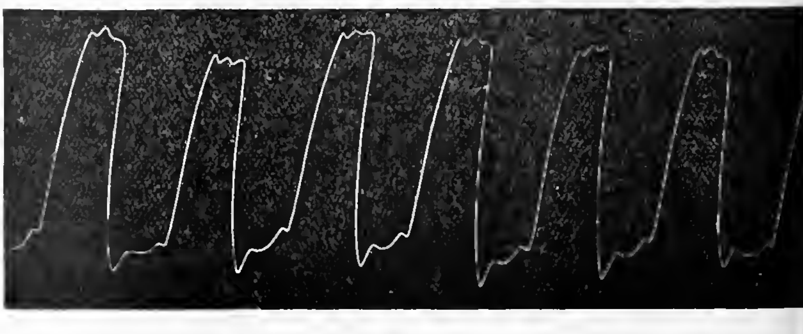

FIG. 4359.—Apex-beat Tracing from Man.

upon the point where the impulse is felt; *r* is a tube opening into the tambour and of a suitable size for the attachment of the connecting rubber tubing. The surrounding outer box, spring, and screw are for regulating the pressure exerted by the button on the skin. The recording tambour (k^2, Fig. 4357) is a similar metal box covered with rubber membrane. Resting upon the centre of the membrane is a support which raises the writing lever when air is driven over from the receiving tambour, k^1. In applying the cardiograph to the heart care must be taken to adjust the button exactly on the apex beat, as an inch or two nearer the middle line the chest wall may recede during the systole instead of being pressed outward, and the tracing obtained would be difficult to interpret. A tracing of the cardiac impulse is shown in Fig. 4359.

A modification of the cardiograph has been made for application to the carotid arteries (Fig. 4360), but for this purpose and also for the venous pulse an ordinary or cup-shaped funnel of suitable size usually suffices.

FIG. 4360.—Receiving Tambour for Carotid Pulse. (Hürthle.)

A small portable kymograph with recording apparatus for two simultaneous tracings is shown in Fig. 4361. The peculiarly shaped receiver *D* is for applying over the edge of the liver to obtain a tracing of the liver pulse.

COMBINED DIRECT AND INDIRECT SPHYGMOGRAPHY.—James Mackenzie has devised an arrangement which he calls "*the clinical polygraph*" (Fig. 4362). In this a recording tambour is attached to a Dudgeon's sphygmograph in such a way that while the radial pulse is being recorded in the ordinary way by direct sphygmography, a tracing of the carotid or jugular pulse or of the apex beat can be recorded over it on the same strip of paper by air transmission. This is a very portable apparatus and is quite delicate enough for obtaining venous pulse tracings. The writer uses an instrument improvised by

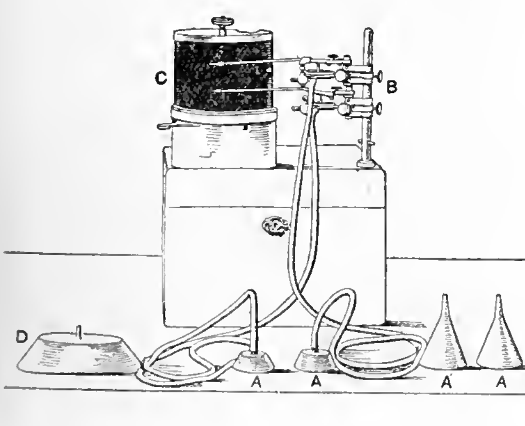

FIG. 4361.—Knoll's Polygraph with Receivers. (Mackenzie.)

himself and his laboratory assistant, but based on Mackenzie's model; with it he took most of the simultaneous tracings figured in the article on *Pulse*. Fig. 4363 shows an example of the radial and external jugular pulses taken simultaneously with this apparatus in a case of dilated heart without valvular lesion. In two of the curves simultaneous points are marked by vertical lines. These points are marked as follows: Before start-

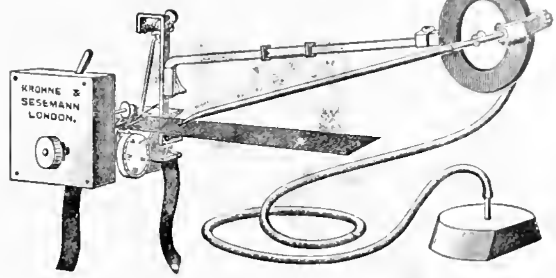

FIG. 4362. The Clinical Polygraph. (Mackenzie.)

ing the paper the two writing levers are allowed to mark vertical lines (× ×, Fig. 4363), to show the relative position of the writing levers. Points on the two tracings equidistant from these vertical lines correspond in time and may be measured off to any desired number. In taking venous tracings the writer usually selects the external jugular, but Mackenzie prefers the internal. The

FIG. 4363.—Simultaneous Tracing of Radial and Jugular Pulses taken by the Combined Method. Jugular above, radial below.

receiving funnel is held over the vein by hand, the amount of pressure required being learned by practice.

A figure illustrating the method of taking the volume pulse (plethsymography) is given in the article on *Circulation*. For further examples of pulse tracings and their interpretation, see article on *Pulse*.

Shenk's "Physiologisches Practicum," James Mackenzie's "Study of the Pulse," T. G. Brodie's "Experimental Physiology," Hutchinson and Rainy's "Clinical Methods," and the catalogues of Baird and Tatlock, London, and Eugen Albrecht, Tübingen.

William S. Morrow.

SPINA BIFIDA.—PATHOLOGY.—Two congenital malformations of the spine, rachischisis and spina bifida are so closely related that they should be considered together. While both are characterized by a deficient formation of the arches of the vertebræ, they differ in the degree of development attained by the spinal cord. In rachischisis it is so rudimentary that even the central canal of the cord has not formed and the endothelium which should line it is exposed as a transparent membrane on the back, through which is seen a flat red area consisting of vascular nerve and connective tissues representing nature's abortive attempt to grow a spinal cord without any axis or "anlage." When the whole cord is involved it is spoken of as rachischisis totalis, amyelia, or absence of the cord; when only a part, partial rachischisis. In spina bifida the cord more nearly approaches its proper development. A hernia like sac of fluid protrudes through the cleft laminæ of the vertebræ; it may or may not contain the cord, spinal roots, and nerves

Rachischisis and spina bifida have their counterpart in the skull and brain: total rachischisis, or amyelia, in cranioschisis or anencephalus, partial rachischisis in derencephalus; the three varieties of spina bifida, me-

FIG. 4364.—Anencephalus with Total Rachischisis. Showing the short neck, upturned face, and dark area medullo-vasculosa in the centre of back; also the area epitheloidea on each side and the mane-like growth of fine hairs.

ningomyelocele, myelocystocele, and spinal meningocele in hydrencephalocele, encephalocele, and meningocele. Furthermore, they are frequently associated and are to be classed as defects of the central nervous system due to arrest of development or persistence of early embryonic conditions, combined with distention of certain cavities with cerebro-spinal fluid.

To better understand the condition spoken of as rachischisis, let us turn to the normal development of the central nervous system in the embryo. The earliest embryonic appearance of the central nervous system is a thickening of the ectoderm in front of the primitive furrow. This thickened area soon bears a longitudinal furrow of its own, which grows rapidly in length while the primitive furrow disappears, and the walls of the furrow grow together on the surface, forming a closed tube, which, however, retains for a long time a direct communication at its posterior end with the cavity of the intestine, while its anterior end expands to form the primitive cerebral vesicles of the rudimentary brain. This embryonic structure is not to be the future cord and brain, but represents the little central canal of the cord and the cerebral vesicles; the real elements of the spinal cord and brain grow around it as an axis. The walls of the neural furrow first coalesce to form a closed tube in what becomes the upper dorsal cord; hence that part is always a little in advance of the rest in its development, and malformations are rarer there than in any other part of the spine. The central canal forms very early. It exists as a closed tube in minute embryos less than one-eighth inch in total length, which, according to the tables of Mall represent about the twelfth day. The beginnings of the vertebral bodies appear later and the arches of the vertebræ still later, so that they project only a short distance from the sides of the vertebral bodies at the end of eight weeks, and it is four weeks more before they unite to enclose the dorsal section of the cord, which is also the first part of the spinal canal to close in.

Fig. 4364 is a photograph of the back of a rachischisic and anencephalic child at term. The cranial vault is wanting, and both the base of the skull and the middle of the back expose an irregular band of dark red, glistening, moist tissue looking like mucous membrane, the area medullo-vasculosa. External to this on each side is a glistening smooth membranous space, the area epitheloidea, merging in turn into normal skin. Outside of this again are a series of small elevations caused by the ends of the cleft arches protruding under the skin, and along this line a band of long, fine, silky hairs grow like a divided mane, extending from the forehead halfway down the back. The back and neck together are very short, the face is turned upward like a frog's, the ears rest on the shoulders, the eyes protrude. A median longitudinal section (Fig. 4365) shows the absence of both spinous processes and spinal cord and an abnormal curve of the cervical spine, which explains the frog-like position of the head on the shoulders. That this position is due to the condition of the spine rather than to deformity of the skull is shown by Fig. 4366, the skeleton of a rachischisic with abnormal cervical curve and a well-developed cranium, whereas Fig. 4367, a median

FIG. 4365. Longitudinal Section through Eight-months' Fœtus with Total Rachischisis. Showing abnormal curves of spine.

section through a fœtus with simple anencephalus, is without abnormal curves of the spine and the position of the head is normal. The study of twenty skeletons of rachischisics in the Warren Medical Museum, Boston, shows that both antero-posterior and lateral spinal curvatures are very common. The cleft in the spine is both wide and long. It is symmetrical, due to absence of the spinous process and of both laminæ; sometimes the transverse processes are unformed. Occasionally the bodies are cleft as well as the arches, so that there is both an anterior and a posterior split in the spine. The halves of the divided spine separate from each other, to unite below the cleft (Fig. 4368). Absence of a vertebra is not uncommon; also segmentation of one or more vertebral bodies, or absence of ribs; deformities of the thorax are common.

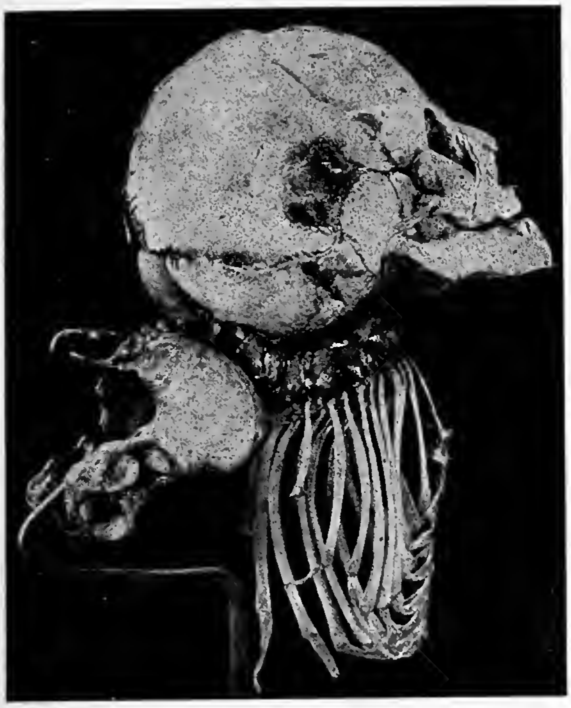

FIG. 4366.—Rachischisis with Great Shortening and Abnormal Antero-posterior Curvatures. Skull well developed. (Warren Museum.)

Partial or incomplete rachischisis may involve any number of vertebræ, from five up, in any part of the spine. Von Recklinghausen (in *Virchow's Archiv für Pathologie*, vol. cv.) describes the appearance of the back. There is absence of skin in a circular area in the median line of the back containing a central dark red area medullo-vasculosa, surrounded by thin glistening membrane which merges into true skin; two dimples, one at the upper and one at the lower part of the area medullo-vasculosa, called cephalic and caudal poles, mark the points where the central canal of the cord commences to be a tube above and below, and a bristle may often be passed into its lumen. Not infrequently a collection of fluid in the meshes of the pia raises this area on the top of a slightly projecting cyst. The appearance is then much like that of a spina bifida.

No surgical procedure has been performed for rachischisis. Most are still-born or die at birth, the rest a few hours after, although a recent case at the Infant's Hospital, Boston, lived eight days, and it is possible that some remain alive longer.

Spina bifida was first correctly described by Nicolai Tulpius, of Amsterdam, in 1685—a congenital malformation consisting of a cleft of the arches of the vertebræ and a sac containing fluid protruding on the back; very rarely there may be a cleft in the bodies of the vertebræ as well as in the arches. The Clinical Society of London in 1885 appointed a special committee to tabulate all the cases recorded in literature, all London hospital records and museum specimens, and incidentally to report on the best method of treatment. Their classification of the different forms of spina bifida is based upon the gross pathological appearances of museum specimens. It divides them into three varieties, according to the position of the fluid: first variety, fluid external to pia mater of cord; second variety, fluid contained in dilated cavities of pia-arachnoid; third variety, fluid within the cord itself in the dilated central canal. The first condition is named spinal meningocele, the second meningomyelocele, and the third myelocystocele. Then there are mixed forms in which a cyst of the cord is associated with one of the other varieties of spina bifida, called by Recklinghausen myelocystomeningocele. They constitute a fourth variety.

Spinal meningoceles represent a fairly large proportion of all cases of spina bifida, but different writers vary in their estimates. This is due to the scarcity of museum specimens, for unlike the other forms the death rate from operation is very low in this variety. The sac is usually large and always globular, either entirely covered with skin or with a relatively small membranous portion on top, while the pedicle is constricted and slender. Such sacs most frequently come in the lumbo-sacral or sacral region, are uncommon in the cervical and lumbar spine, and are rare in the dorsal region. The cleft is always small, involving only one or two vertebræ, is situated a little to one side of the median line, and the pedicle of the sac may even escape through a deficiency of the ligaments between well-formed arches of adjacent vertebræ. On opening it, a loop of cord or nerves may be found lying in the neck of the sac. Clinically the absence of subdivisions and of large nerves may be demonstrated by applying the hydroscope to the sac in the same manner as one would apply it in a case of hydrocele. The skin surrounding the base of the sac is usually covered with a growth of silky hairs.

FIG. 4367.—Longitudinal Section through Anencephalic Fœtus. Showing almost normal spinal curves.

Myelomeningoceles.—These are common in the lower segments of the spine, less common in the dorsal, and very rare in the cervical region. The cleft is large, involving the arches of four, five, six, or even seven vertebræ. The sac, therefore, has a wide base, and as it is usually subdivided by partitions into a number of chambers it has an irregular, more or less flattened contour. The external covering consists of both skin and membrane, but the summit and a considerable part of the walls are membranous. The skin about the base is hairy and often too thin and poor to make good flaps in operating. The sac contains cerebro-spinal fluid, spinal roots, spinal nerves, and the cord itself, except in a few cases in which the cauda equina alone enters. Sometimes the cord runs through without attaching itself to the sac; usually it is attached. The attachment shows externally as an umbilication of the summit, and was first described by Virchow in 1863. Internally the cord is greatly deformed and spreads itself out on the top of the sac, becoming indistinguishable from it save for the nerve roots that spring from it and traverse the cavity in long loops to reach their respective intervertebral foramina. This appearance is shown in Fig. 4371, where the sac has been opened by a vertical median incision. The nerve roots and nerves show plainly, unless there are numerous subdividing cross walls, as in Fig. 4372, which, however, is not uncommon. The nerves are seldom normal in appearance, at times they are very thin, and at other times very thick, translucent, red, and semitransparent from œdema; this swollen condition often corresponds to an absence of axis cylinders and explains paralysis. Clinically, myelomeningocele may be differentiated from simple meningocele by the shape of the tumor, the broad base, and irregular form, if umbilicated resembling a tomato, and the largely membranous covering; the presence of the cord, of nerves, and of septa may be inferred from shadows seen by examining the sac with the hydroscope, also by applying with a small electrode a mild faradic current to different points on the surface of the sac. On the summit, often close to the umbilication, one frequently finds superficial ulcers with a granulating base either round or irregular in contour, the appearance is suggestive of partial rachischisis, and it has been thought that the ulcer, which often corresponds to the attachment of the cord, is in reality an area medullo-vasculosa. The author has recently studied four such cases, but ... is unable to demonstrate on any of them the presence of the cephalic or caudal dimple of Recklinghausen.

FIG. 4368.—Cleft of Bodies of Cervical and Seven Upper Dorsal Vertebræ with Separation; Great Shortening and Deformity of the Thorax and Neck. Anterior aspect. (Warren Museum.)

Myelocystocele and Myelocystomeningocele.—Myelocystoceles, where the fluid lies wholly in the distended central canal of the cord, are very rare. The committee of the Clinical Society found but two uncomplicated cases. They were in the cervical and lumbar regions. Recklinghausen speaks of eleven cases and noted the occurrence of a large hernia of the abdominal contents, *bauch-darm-blase-spalte*, in ten of them. These cases were, however, not pure myelocystoceles, for they were associated with fluid in the meshes of the pia-arachnoid and were classified by him as belonging to the fourth variety of spina bifida, called myelocystomeningocele. These are of four kinds:

1. A cystic cord with a spinal meningocele lying on its dorsal side.

2. A cystic cord squeezed up out of the spinal canal by a meningeal cyst beneath it.

3. A rupture of the cystic cord into a meningeal cyst, the cord where it is split open exposing the lining of its central canal like the area medullo-vasculosa, only it is exposed in the interior of the spina bifida sac instead of externally to the air.

4. A distended cord lifted upon a meningeal cyst bursts externally, leaving on top of a spina bifida sac a small sinus opening into the central canal.

In pure myelocystoceles the vertical split involves only one or two arches, while in the myelocystomeningoceles four to six may be deficient. The covering consists of skin, fat, subcutaneous and deep fascia, aponeurosis, and tissue of the spinal cord; in other words, it is thick enough to be opaque when viewed by transmitted light. The cavity is glistening, smooth, and regular, without any nerves or bands traversing it. The spinal roots arise from the outside of the sac anteriorly. Simple spinal meningocele differs from it clinically chiefly in the thinness and translucency of the sac wall. Myelocystocele, however, is accompanied by conspicuous curvatures of the spine, absence or deformity of ribs, the great congenital hernia already alluded to, also club foot, paraplegia, and paralysis of the sphincters. The presence of a number of other deformities or of extensive paralysis involving the sphincters may raise the presumption, in a doubtful case,

FIG. 4369.—Rachischisis with Lateral Curvature. The arches of the cervical spine are closed. (Warren Museum.)

that we are dealing with a myelocystocele or a myelocystomeningocele.

Differential Diagnosis.—There are distinct differences in the physical characteristics of the varieties of spina bifida—differences great enough to enable the surgeon to guess shrewdly before operating what he will find in the sac and to guide him in selecting a method of procedure adapted to the conditions confronting him. His opinion is to be based on an examination of the tumor, of the presence and extent of paralysis, and on the presence of other congenital deformities. The form, size, and location of the tumor, the character and thickness of its covering, its translucency, the presence of shadows indicating partitions or nerves in the sac, when examined with the hydroscope by transmitted light, the size of the pedicle or base, and the number of deficient vertebral arches—all these together afford valuable evidence of the variety of spina bifida one is dealing with, while the presence of extensive grave malformations and paralysis confirm and correct the diagnosis. The table given below may be of use.

Fig. 4370.—Spina Bifida in Child of Five Years. Deficiency of sacral arches. Probably a myelomeningocele. (Warren Museum.)

Natural History.—What is the natural life of spinæ bifidæ if they are unoperated and receive home care? How much does the deformity interfere with the enjoyment of life, and what proportion live to be adults? It may be stated without hesitation that only a small proportion live to adult life. The mortality in the first year is very great; in London the mortality returns for a single year show that out of 89 deaths from spina bifida 86 were under a year old, and the death rate is much higher during the first three months than for the rest of the year. The chief causes of death are rupture of the sac, meningitis, convulsions, marasmus, hydrocephalus; intercurrent affections play a subordinate rôle. Of 32 untreated cases followed by Demme, of Berne, all of whom died under two years old, 15 children died from rupture of the sac, 10 from marasmus, and 7 from intercurrent diseases. Out of 60 unoperated cases collected by Marsh, Gould, Clutton, and Parker, there were 3 deaths in adults (most of the cases were children), 1 from spontaneous rupture and meningitis, 1 from stone in the bladder, 1 from unknown cause. Rupture and meningitis are undoubtedly the largest factors in the death rate both of children and of adults.

Fig. 4371.—Section through a Myelomeningocele. The lumbar enlargement is attached to the posterior wall of the sac, and has been divided. The nerve roots are seen running from this part of the posterior sac wall toward the foramina. (Warren Museum.)

When a child survives the first few years, the tumor either persists or undergoes spontaneous cure by shrink-

Aids in Differentiating Varieties of Spina Bifida.

	Spinal Meningocele.	Meningomyelocele.	Myelocystocele Pure.	Myelocystomeningocele.
Form	Globular or nearly so	Irregular, slightly lobulated, often with umbilication.	Globular	Irregular, often higher than broad.
Size	Plum to child's head	Small plum to orange	Plum to ?	Plum to orange.
Location	Lower lumbar and sacral, uncommon cervical and rarely dorsal.	Lumbar and sacral, rare in cervical and dorsal.	Lumbar, sacral, cervical	Cervical, lumbar, sacral
Thickness of sac	Thin	Thin	Thick	Thick.
Character of covering	Skin sometimes with a small part membranous.	Usually more membrane than skin. Rarely skin covered, frequently ulcerated.	Skin	Skin or part membrane.

Other malformations	Usually absent	Usually present	Usually some, not very grave.	Usually present, grave; abdominal hernia common.

age. However, out of eight adults and three children in whom the tumor persisted untreated there was only one who could say that he had no ill effects from it. Spontaneous cure I have observed to take place after superficial ulcers on the surface of the sac had cicatrized; scar contraction seemed to be the chief factor in shrinking the tumor. Spontaneous cure has also followed rupture of the sac, but it is a surprising result, for this is usually a fatal accident. Spina bifida is very often associated with other malformations and deformities from paralysis, conditions not benefited by spontaneous cure.

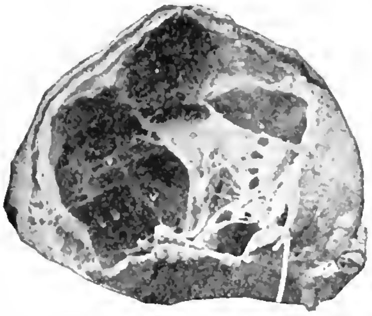

FIG. 4372.—Myelomeningocele: Sac much Subdivided. (Warren Museum.)

TREATMENT.—Without surgical intervention the chance of life for a young baby with spina bifida is small. His chance improves as he grows older, but his chance of living a useful, industrious life is slim; he will be an invalid nine times out of ten if he lives. Does surgery offer any better outlook? What is the mortality in cases which undergo operation? The recently compiled statistics of Swedish surgeons show that out of 229 cases which underwent operation 82 were fatal, a mortality of 35.8 per cent. Out of 21 cases over five years old but 1 was lost, while 43.3 per cent. of the cases under a week old ended in death. It is impossible to fix a mortality rate for the different forms of spina bifida, because clinical records have been made without reference to its division into varieties; for this reason some writers assert that about all children with spina bifida die before they are a year old; other surgeons whose experience is limited to a few successful operations believe that it is a simple thing to cure them all. In a measure both are right.

Simple meningoceles if protected against rupture not infrequently get well by gradual obliteration of the pedicle with fibrous tissue and subsequent shrinkage from absorption of fluid. If the meningocele is ruptured, whether during birth or afterward, convulsions and death from septic meningitis follow as a rule, unless the sac be ligatured and excised promptly to prevent the infection of the spinal canal. At least four cases, however, of rupture have been known to have healed without infection with a spontaneous cure. The fear of rupture often leads to excision of the sac, and the great majority of these cases make a perfectly good recovery. Nicoll, of Glasgow (*Lancet*, 1901, vol. i., p. 615), reports a good result in three cases, all in the cervical region, operated in the outpatient department and sent to their homes where a trained nurse attended them. The children were treated in this way rather than in the hospital ward because they were nursing and their mothers could not be admitted with them. A recent Italian writer reports a cure following repeated aspirations of a lumbar case. Hydrocephalus sometimes makes its appearance in a few weeks after operation and is a very unfavorable prognostic sign, just as it is in the other forms of spina bifida. The surgical technique for excision of a simple spinal meningocele presents no difficulties. The skin, subcutaneous fat, and fascia are divided on the tumor about an inch above the true pedicle, and the dissection is carried down to where the pedicle emerges and a ligature of silk or catgut loosely placed around it; the sac is then opened by a median incision and part of the fluid in it emptied in order to see if the cord or nerves are looped into the sac where the ligature might constrict them; if so, they should be gently tucked back into the canal with a probe or the ligature raised upon the pedicle sufficiently to avoid them before tying and excising the sac. If more than one vertebral arch is deficient, flaps from the aponeurosis covering the muscles of the back should be turned up and stitched over the pedicle, then the skin is sutured and a sterilized gauze dressing applied. If the patient is a young baby, loss of heat is to be guarded against during the operation by laying the infant face downward on a couple of hot-water bottles at about 110° F., and extra care should be taken to guard against shock. Anæsthesia should not be pushed too far with young babies, as it is easy to produce profound narcosis.

In England twenty years ago the injection of Morton's iodoglycerin solution was extensively employed. Dr. James Morton, the inventor, claimed to have obtained well-marked shrinkage and obliteration of the sac in forty out of fifty consecutive cases. The solution is made by dissolving ten grains of iodine and a drachm of iodide of potassium in an ounce of glycerin. One drachm of this is slowly injected with a hypodermic syringe into the sac; the child is held with the back down during operation and for several hours after, a precaution to prevent the fluid diffusing by gravity into the spinal canal. Sudden death followed occasionally; large clefts of the lumbosacral region were considered dangerous. The application of an elastic ligature has been abandoned in favor of cleaner and more modern methods.

Meningomyelocele is a much graver malformation, because with very few exceptions the cord is deformed where it is attached to the sac; the deformed region frequently involves the origins of six or more pairs of spinal roots; where the cord itself is not attached the nerve roots are adherent and are drawn out into long loops. Partial paraplegia and paralytic club-foot are commonly associated with it, as might be expected, and not infrequently congenital dislocation of the hip. No improvement of the paralytic condition has been obtained from operations upon the sac in this class of cases. Is it not wiser to refrain from operating? This question would certainly receive an affirmative answer were no other point of view obtainable. Most patients with meningomyelocele die during the first year of life; the chief causes are septic meningitis from rupture or ulceration, and hydrocephalus. Operation is justifiable if either of these causes of death can be eliminated. Hydrocephalus can neither be eliminated nor improved by operation, but a tight covering of healthy skin can be substituted for a thin ulcerating membrane in many cases and the danger of infection and rupture removed. Operations are often undertaken with only this end in view, and two methods have been successfully used—the injection of the sac with iodine and the cutting operation miscalled excision. The former method has just been described. The latter operation is performed somewhat differently from that employed for spinal meningocele. It consists in laying out as large skin flaps as possible from the base of the tumor and removing if possible the thin outer layer of membrane covering the vault of the tumor without opening the sac. The latter is then opened by a small incision somewhere on the side to avoid injuring the nerve roots and cord; the flaps are prepared from the muscle aponeurosis and tightly stitched over the collapsed sac; the skin is sutured over it with a layer of superficial stitches. In children of the age of puberty flaps of bone are often turned in to prevent the subsequent bulging which is bound to come on account of the large size of the cleft; foreign bodies have also been employed—pieces of gold or celluloid. The main object of the operation, however, must be to unite the divided sac and the skin flaps in such a way as to avoid leakage of cerebro-spinal fluid and not to injure the cord and nerves in replacing them in the canal. On account of these real difficulties the prognosis before operation must be much less favorable than in a case of simple meningocele. The after-care should also embrace every precaution to prevent leakage until union may take place. Little babies are best kept face down on the nurse's lap for six to ten hours, and then kept in bed still on the face with the hips raised for six days. Feeding in this position is difficult, but may be accomplished by using the old-fashioned nursing-bottle with long flexible tube.

Myelocystocele pure and simple is fortunately a very rare deformity. Dr. Morton greatly improved one case by iodine injections. Aspiration alone or the evacuation of fluid by simple incision would inflict very little injury on the cord; but operators are wary of doing anything which might produce an increase of the paralysis, especially as a tough healthy skin covering, affording good protection against rupture, is usually found. After a small incision had been made, aponeurotic flaps could be turned back and closely sutured to prevent leakage of cerebrospinal fluid, as is done for meningomyelocele; the thickness of the skin flaps also would aid in preventing leakage. The myelocystomeningocele of Recklinghausen or myelocystocele complicated by meningomyelocele or by spinal meningocele is less common than either of those varieties. As the anatomical conditions vary widely treatment must be varied to suit the individual case. It was Mr. Clutton's intention, if he should find the sac becoming smaller, in a case in which a meningeal cyst was lying on the dorsal side of a myelocystocele, to inject Morton's solution. Excision of the meningocele could be performed in such a case, but the dilated cord would be too big to be replaced in the spinal canal.

In case the position is reversed and the hydromyelocele is on the dorsal side of a meningeal cyst, the same difficulty renders replacement of the cord into the canal impossible, although if impending rupture or danger of septic meningitis make operation imperative, an operation similar to that described for meningomyeloceles may be performed, the surgeon taking large enough flaps from the muscle aponeurosis to cover in the collapsed cysts which would probably be too voluminous to re-enter the canal. Unless these dangers threaten, however, cases are better unoperated, especially if the healthy skin covers the sac. A shield of metal, hard rubber, or stiffened leather should be worn to protect the sac from pressure. In case we have to deal with a myelocystocele which has ruptured on its ventral side into a subjacent meningeal cyst, the condition cannot be differentiated clinically from meningomyelocele and the treatment should be the same. In case the rupture has come on the dorsal side, leaving the sinus connecting the central canal of the cord with the external surface of the sac, it would seem rational first to explore, lay open, and obliterate the sinus, provided it is not too long, before attempting to deal with the sac itself. Curiously enough, several cases have been reported of adults who have borne these sinuses all their lives; it is probable that in these cases the sinus is limited by a closure of the central canal not far from the orifice.

In deciding on the treatment for a case it is well for the surgeon to ask himself three questions: Is this a case in which no operation should be done, or is it one in which a successful operation is possible, or one in which operation has to be done as a life-saving measure? No operation should be performed if the tumor is decreasing in size without leaking, unless meningitis is feared from the presence of deep ulcers; because a natural spontaneous cure offers just as good a result to the patient as does an operation. No operation should be performed if hydrocephalus be present, except with the distinct understanding that it is undertaken to avert for a short time death from rupture or meningitis. No operation should be performed on a myelocystocele which has a thick covering of healthy skin unless it is rapidly enlarging. Operation may be successful in any other case, whether spinal meningocele, myelomeningocele, myelocystocele, or myelocystomeningocele. Simple spinal meningoceles are almost always much benefited by excision. Excision should be done as a life-saving measure in all cases of rupture, and it should be done as soon as possible after the rupture; it should be done as a life-saving measure whenever rupture seems imminent or the proximity of septic ulcers awakens just fears of septic infection spreading to the meninges.

Temporary relief from impending rupture may be obtained by aspiration if the child's condition renders operation unjustifiable.

Spina Bifida Occulta.—In the so-called spina bifida occulta there is no projecting sac; an abnormal hairy patch in the median line is usually the only external sign on the back. Some paralysis, or paresis, a paralytic club-foot, muscular atrophy of the limb, anæsthetic areas, or sphincter paralysis which cannot be logically accounted for in other ways, may lead to its recognition; in some cases peculiar ulcers of the foot of nervous origin are observed. The affection is frequently obscure unless the bare back is seen. Sometimes a soft mass like a diffused lipoma may be felt beneath the hairy patch.

Recklinghausen says, in explanation of this condition, that in fœtal life there was present a spina bifida which collapsed and shrivelled, leaving only a minute scar and the hypertrichosis to mark where it had once been. On dissection one, two, or three cleft vertebræ are found closed in with a thick, dense, fibrous membrane, like a drum head. This is perforated by a fibrous or fibromuscular band uniting the superficial part of the tumor with that lying within the spinal canal; for a tumor, usually a fibro-lipoma, has been found at autopsy in these cases, and not infrequently considerable softening or compression of the cord as a result of its growth. The removal of this tumor and of fibrous tissue bands has in a few instances been followed by a complete disappearance of paralysis. One case was reported by Robert Jones in 1889. The lumbar cord in spina bifida occulta extends in the spinal canal often to the lower part of the sacrum instead of ending opposite the first or second lumbar vertebra. No explanation has been offered for the cause of the hypertrichosis. The tumor is regarded by Recklinghausen as the growth of some embryonic cells which had been drawn into the spinal canal along with the collapsed spina bifida sac. These cells may at times belong to another embryo and give rise to cases of fœtal inclusion like that reported by Jones, who removed a third arm from between the scapulæ and in so doing opened the spinal canal. *Augustus Thorndike.*

SPINAL COCAINIZATION AND LUMBAR PUNCTURE.—Analgesia by the subarachnoid injection of cocaine was first demonstrated by Dr. J. Leonard Corning, of New York, in 1885, and since that date this method of inducing anæsthesia has been carefully elaborated and has been practised in several thousand recorded cases by numerous observers in various parts of the world.

The knowledge so far accumulated does not justify a strict comparison of this procedure with general anæsthesia by ether or chloroform inhalation, and its relative safety is not yet definitely determined, but the meagre and fragmentary statistical data at present available indicate a mortality considerably in excess of that attendant upon the use of chloroform, and it is more than probable that the vast majority of practical surgeons do not, for various reasons, indorse the procedure as a trustworthy expedient. The more conservative advocates of this measure, being mindful of the hazard, regard it, not as a substitute for other methods of producing anæsthesia, but rather as appropriate to cases in which local anæsthesia cannot be applied, or when general anæsthetic agents are clearly contraindicated in consequence of pulmonary, cardiac, or renal disease, in aged persons, in alcoholics, in operations of a class rendered extra-hazardous by the administration of a general anæsthetic, and in operations in which the concurrence or the consciousness of the patient is desirable or necessary.

In the hands of prudent men, immediately disastrous results have been few, although alarming symptoms and sudden death, inexplicable on any other hypothesis than that of shock or intoxication, have followed lumbar puncture, both without and after the cocaine injection, thus clearly establishing the fact that the procedure is by no means free from danger.

It is worthy of remark that a number of failures have been reported, but how far the negative or the unfavorable results have been influenced by faulty technique, by impure cocaine, or by idiosyncrasy is not known, and the possibility of provoking by puncture remote pathological changes in the cord or in its membranes remains to be ascertained.

Spinal cocainization is commonly resorted to for the purpose of producing analgesia in those parts of the body which are below the diaphragm, but it is claimed that the effect may be extended to the upper part of the trunk, to the head, neck, and upper extremities, and that it is available for operations upon these parts as well as for major and minor abdominal and pelvic operations, and for other operations on the lower portions of the body.

Various substances possessing more or less analgesic power have been used in like manner for the same purpose. Among them, eucaine, antipyrin, nirvanin, and morphine; but cocaine is employed far more than all the others combined, and is decidedly to be preferred for this purpose to any known agent.

A drug introduced into the subarachnoid space should be absolutely sterile, as the risk of infection ranks among the prominent dangers of the practice. It should also be of pure quality and of definite strength. Several methods of rendering cocaine aseptic have been proposed and have proven satisfactory. Most operators who undertake to sterilize the drug depend upon heat applied to an aqueous solution, using a temperature of 180° to 212° F., for from one minute, which does not sterilize, to fifteen minutes, which is said to destroy much of the cocaine and seriously to impair the analgesic property of the solution thus treated. The method of fractional sterilization of a two-per-cent. solution by subjecting it, in glass capsules, to a heat of 176° F. for four hours, on four successive days, is efficient, but very troublesome, as the solution does not keep well and is generally regarded unfit for use after about two weeks, so that a fresh preparation of the drug becomes necessary. The dry method appears to be the most feasible. This consists in subjecting a chemically pure specimen of cocaine to a dry heat of 300° F. for ten minutes or longer. The powder is not decomposed or injuriously affected by this temperature, and if properly protected it will keep indefinitely and is always ready for use.

The usual dose for a robust adult is from one-quarter to one-half of a grain, dissolved either in sterile water or in the spinal fluid itself. Smaller doses are recommended for young, very old, or feeble subjects. A two-per-cent. solution is ordinarily employed—the smaller dose of a stronger solution being generally preferred to a corresponding dose of a weaker solution.

The use of cocaine by spinal injection is not restricted, exclusively, to surgical procedures. It has been successfully employed in obstetric practice for the purpose of lessening the pains of parturition. The injection is made during the second stage, and it is claimed that the pains are relieved, while at the same time the force of the uterine contractions is not diminished, but that voluntary effort, on the other hand, is increased—the suffering being absent—so that the duration of the labor is thereby actually decreased.

Some of the ardent supporters of medullary narcosis attribute to it, if promptly invoked, the power to limit or to arrest shock from violent injuries.

The anaesthetic effect of an average injection of cocaine is felt in the lower portions of the body after three or five to ten minutes. The upper portions of the body are affected in from twenty to thirty minutes, and the maximum dose is usually required to accomplish this result. Complete insensibility to pain may continue for from one hour to one hour and a half or two hours, and sometimes for three, four, or even five hours. In prolonged operations or in tedious labor, the injection may be repeated, in a slightly decreased dose, if necessary to maintain the anaesthesia.

A glass syringe which can be boiled and rendered thoroughly aseptic fulfils the requirements of a satisfactory instrument. The needle should not be less than three inches long, of small diameter, with a sharp point and a short bevel. It may be constructed of steel or of a composition of iridium and platinum, which is strong, not brittle, and is less likely to rust than steel.

Subarachnoid injection, whether with cocaine or with any other substance, is liable to be attended by more or less serious symptoms—by untoward phenomena associated either with the simple puncture or with the effect of the injected material. Among the most important manifestations are cardio-respiratory disturbances, asphyxia, panting, shock, headache, restlessness, delirium, rapid pulse, nausea, vomiting, sweating, cyanosis, collapse, cramps, rigors, transient paraplegia, sensations of heat, general depression, elevated temperature, subnormal temperature, fibrillary muscular contractions, relaxation of the sphincters with involuntary discharges, retention of urine, etc.

In very nervous and apprehensive patients, the eyes and ears should be closed during the operation, and a dose of morphine and strychnine, given as a preliminary safeguard, is sometimes advantageous. The instruments, the hands of the operator, and the skin over the entire back and loins of the patient should be prepared as carefully as for an abdominal section. Any of the lumbar interspaces may be selected for the puncture, though the third or fourth is usually chosen. It has been done as high as the sixth cervical vertebra, but it is generally conceded that under ordinary circumstances puncture in the lumbar region is safest and best, even when high analgesia is desired. The spinous process of the fourth lumbar vertebra can be located by drawing a transverse line to connect the two iliac crests. It may then be accurately defined by deep palpation. The seat of puncture should be frozen by ethyl chloride, and the skin—the only sensitive tissue—penetrated with the point of a bistoury. The patient should lie on either side, with the body well curved forward and a pillow under the hip. The needle may be entered just beneath the spine in the median line and pressed firmly a little upward and forward, or it may be entered a half-inch to the right or to the left of the median line and passed obliquely toward the spinal canal. When the point of the needle enters the space, which in a well-developed adult is about two and a half inches below the surface, a sense of diminished resistance will be noticed, and the spinal fluid, always clear and limpid, will flow from the outer end, drop by drop or in a steady stream. If the lumen of the needle should be obstructed or if from any cause the fluid does not appear after the point is supposed to have entered the space, a stylet may be passed, the patient may cough or make a slight straining effort, or gentle aspiration by means of a syringe will overcome the obstacle. When the fluid begins to flow, the finger should be placed over the end of the needle, and the syringe containing the warm solution or the sterilized crystals of cocaine should be attached. Operators of experience disagree as to the advisability of allowing a few drops of the fluid to escape before throwing in the cocaine solution, some alleging that the normal quantity of the fluid in the cavity should not be disturbed, but that the amount withdrawn should equal or slightly exceed the amount introduced, while others assert that severe headaches and other bad effects are infrequent if the spinal fluid is not wasted. If the solution is used, the piston should be slowly depressed, but if the powder is to be dissolved in the spinal fluid the piston, already closed, should first be withdrawn until the barrel is about half filled with the fluid, which readily dissolves the cocaine, and then the solution should be gradually returned into the space, the needle removed, and the puncture closed with collodion.

Emphasis is laid upon the importance of very deliberate introduction of the solution, and a little delay in withdrawing the needle is advised; if, however, analgesia of the upper parts of the body is desired, the very rapid and forcible depression of the piston is considered essential.

Lumbar puncture, as an independent procedure for the purpose of withdrawing cerebro-spinal fluid, was introduced to the profession by Quincke in 1890, and since then it has been frequently practised as a diagnostic means and to lessen pressure in acute or chronic hydrocephalus.

It should be remembered that the spinal cord proper terminates at the first lumbar vertebra, and that the subarachnoid space is continuous with the ventricles of the brain through the foramina of Magendie, Key and Retzius. It is not certain, however, that these foramina are always sufficiently patent to allow the free passage of the fluid. The normal quantity of the cerebro-spinal fluid varies in different individuals. It has been estimated at from half an ounce to two ounces. It is more abundant in old than in young persons, and is quickly reproduced.

The operation of lumbar puncture is simple and easy of performance, but it is attended with considerable danger. The withdrawal of a very small amount of cerebro-spinal fluid has caused extremely grave symptoms, and has been followed in repeated instances by immediately fatal results. The puncture is usually made, with strict antiseptic precautions, at the third or fourth lumbar interspace as above described for spinal anesthesia. *James B. Baird.*

SPINAL CORD.—*General Description of the Macroscopic Appearances.*—The spinal cord (*medulla spinalis*) (Figs. 4373, 4374, and 4375) is that portion of the central cerebro-spinal nervous system which is situated within the vertebral canal. In human beings it is a slightly flattened cylindrical strand, varying in calibre somewhat at different levels. It is markedly curved in its course, corresponding to the curvature of the vertebral column. The spinal cord measures from 43 to 45 cm. in length, being on the average somewhat longer in the male than in the female. It is continuous above, at the lower edge of the foramen magnum, with the medulla oblongata, and extends below into the lumbar part of the vertebral canal, where it is suddenly drawn out into a terminal filament (*filum terminale*). The lower limit of the cord is variable in position in human beings. Usually the junction with the terminal filament is met with opposite the lower third of the first lumbar vertebra, or opposite the upper third of the second lumbar vertebra, but it may be found even higher or lower than these levels. In the adult, therefore, the spinal cord does not extend throughout the whole length of the vertebral canal; the condition is very different from that found in the embryo (*vide infra*). Nor does the spinal cord come anywhere near filling up the lumen of the vertebral canal. A cross section through the vertebral canal with the cord *in situ* reveals a large space between the surface of the cord and the inner surface of the bony vertebral canal (Fig. 4374). This space is subdivided by the coverings of the cord into several spaces. One of these, between the arachnoid membrane and the pia mater, the so-called subarachnoid cavity (*cavum subarachnoidale*), is filled with the cerebro-spinal fluid (*liquor cerebrospinalis*). This disproportion between the size of the cord and that of the cavity of the vertebral canal is of great significance for the protection of the cord from injury during the various movements which the vertebral column undergoes.

The spinal cord, though in general of a cylindrical shape, is everywhere somewhat flattened from before backward; the sagittal diameter is always less than the frontal diameter. In the smallest portions of the cord the difference between the sagittal and frontal diameters may not exceed 1 or 2 mm., but in the two enlargements of the cord the difference may be much greater. The upper principal enlargement is situated at the junction of the neck and thorax, and is known as the cervical enlargement (*intumescentia cervicalis*); at the point of its maximal enlargement the frontal diameter exceeds the sagittal by 4–5 mm. The other principal enlargement, at the junction of the thoracic with the lumbar spine, is known as the lumbar enlargement (*intumescentia lumbalis*); the maximum of this enlargement is reached at the level of the twelfth thoracic vertebra, where the frontal diameter exceeds the sagittal by 2.5–4.5 mm. These two principal enlargements correspond to the places where the spinal cord gives off nerves to, and receives nerves from, the upper and lower extremities respectively.

Just below the intumescentia lumbalis the spinal cord diminishes very rapidly in calibre, giving rise to the so-

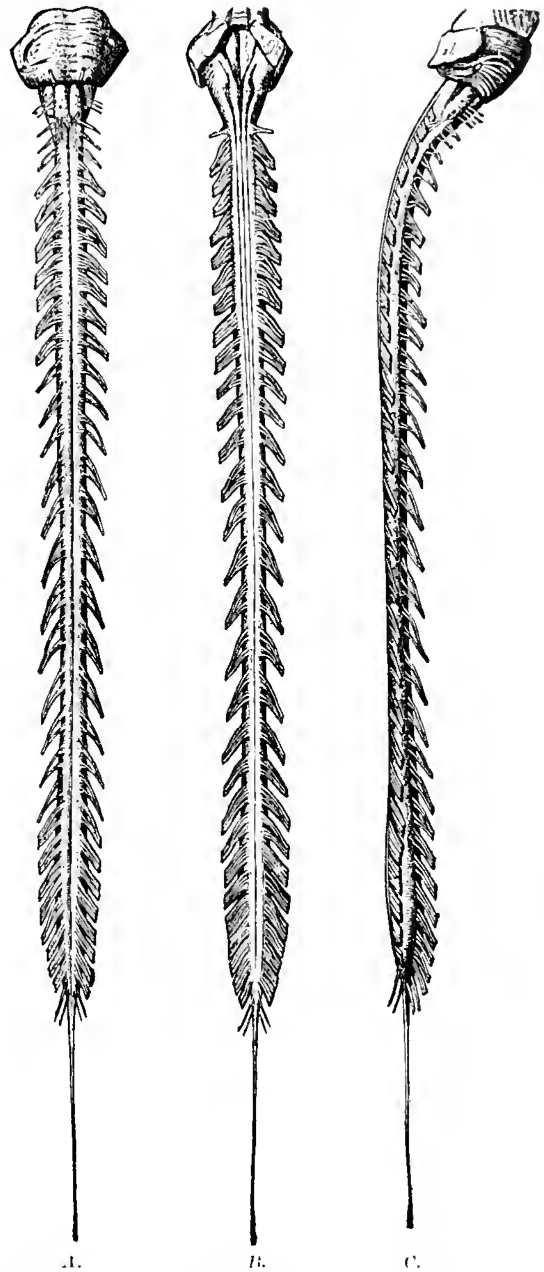

FIG. 4373.—Views of the Spinal Cord (Medulla spinalis). *A*, From in front; *B*, from behind; *C*, from the right side. (From Toldt.)

called medullary cone (*conus medullaris*). From the lower end of the conus medullaris the terminal thread (*filum terminale*) extends downward as a delicate strand for a distance of from 20 to 25 cm., to terminate upon the posterior surface of the os coccygis (Fig. 4375).

The spinal cord weighs on the average from 27 to 28 gm., but in individual cases the weight may be considerably above or below the average.

The external surface of the cord is not perfectly smooth. On examination, a deep longitudinal groove is seen in the median line upon the anterior surface. This is

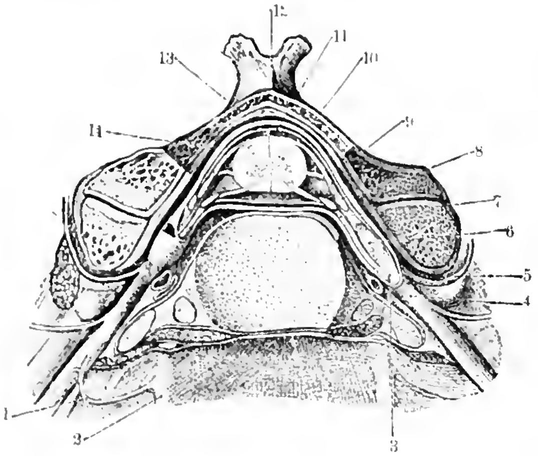

FIG. 4374.—Transverse Section Through the Intervertebral Fibro-Cartilage Between the Third and Fourth Cervical Vertebræ. The spinal meninges are shown in cross-section and their relations to the spinal nerves are indicated. (After C. Toldt, "Anatomischer Atlas," Wien, 1900.) 1, Ramus communicans; 2, trunk of the sympathetic; 3, fourth spinal nerve; 4, ramus anterior; 5, ramus posterior; 6, ganglion spinale; 7, radix anterior; 8, radix posterior; 9, spinal dura mater; 10, subarachnoid space; 11, spinal arachnoid; 12, spinous process of the third cervical vertebra; 13, subdural space; 14, epidural space.

known as the anterior median fissure (*fissura mediana anterior*). In the median line, on the posterior surface of the cord, there is no such deep groove, but only a shallow sulcus called the posterior median sulcus (*sulcus medianus posterior*). These anterior and posterior median sulci indicate the line of subdivision between the two symmetrical halves of the cord—the right and left halves of the spinal cord.

Attached to the surface of the cord are the radicular threads (*fila radicularia*) of the roots (*radices*) of the spinal nerves (*Nn. spinales*). These are arranged in four rows, two ventral or anterior and two dorsal or posterior. These rows of the fila radicularia unite to form roots which are spoken of respectively as the anterior or ventral roots (*radices anteriores seu ventrales*) and the posterior or dorsal roots (*radices posteriores seu dorsales*). Lateralward each ventral root unites with a dorsal root of the same side and level to form a single trunk, the spinal nerve (*N. spinalis*). On each dorsal root, just before its union with a ventral root, is a distinct swelling, the so-called spinal ganglion (*ganglion spinale*). The fila radicularia of the anterior or ventral roots of the spinal nerves leave the spinal cord along a longitudinal area situated a little lateralward from the anterior median fissure; though there is, in reality, very little if any depression of the surface at the points of exit of the anterior or ventral roots, a shallow groove has been described here and designated the anterior lateral sulcus (*sulcus lateralis anterior*). Behind, however, a few millimetres laterad from the sulcus medianus posterior on each side and corresponding to the line of the fila radicularia of the posterior or dorsal roots, there is a distinct groove, called the posterior lateral sulcus (*sulcus lateralis posterior*).

These longitudinal sulci, running the whole length of the cord, subdivide its surface into strands which are known as funiculi (*funiculi medullæ spinalis*). Of these funiculi there are three for each half of the cord. Thus between the fissura mediana anterior and the sulcus lateralis anterior is situated the anterior funiculus (*funiculus anterior*); between the sulcus lateralis anterior and the sulcus lateralis posterior of the same half of the cord is situated the lateral funiculus (*funiculus lateralis*); and, finally, between the sulcus lateralis posterior and the sulcus medianus posterior is situated the posterior funiculus (*funiculus posterior*). In the upper part of the spinal cord the funiculus posterior on each side is further subdivided by an additional sulcus known as the posterior intermediary sulcus (*sulcus intermedius posterior*). The lateral portion of the funiculus posterior included between the sulcus lateralis posterior and the sulcus intermedius posterior is known as the wedge-shaped funiculus (*funiculus cuneatus*). The medial portion, situated between the sulcus intermedius posterior and the sulcus medianus posterior, is known as the delicate funiculus (*funiculus gracilis*).*

Besides the fila radicularia of the anterior and posterior roots of the spinal nerves, there can be made out in the uppermost part of the spinal cord a few fila radicularia coming off from the lateral surface between the anterior and posterior lateral sulci; these unite to form on each side a nerve trunk which passes upward in the vertebral canal to enter the cranial cavity through the foramen magnum. These fila radicularia belong to the so-called accessory nerve (*N. accessorius*) or eleventh cerebral nerve.

Since the time of Sir Charles Bell, it has been customary to speak of the anterior or ventral roots as *motor roots*, of the posterior or dorsal roots as *sensory roots*, and of the spinal nerves resulting from the fusion of anterior and posterior roots as the *mixed nerve trunks*.

The mixed nerve trunk leaves the vertebral canal through the corresponding intervertebral foramen (*foramen intervertebrale*). In some parts of the cord the corresponding intervertebral foramen lies in a horizontal direction from the fila radicularia of the nerve, but in other parts of the cord, owing to greater rapidity of growth at certain periods of development of the bony vertebral canal than of the spinal cord itself, the intervertebral foramina are situated at much lower levels than are the fila radicularia of the corresponding spinal nerves. The result is that certain of the spinal nerves follow a more or less markedly oblique course between the cord and the intervertebral foramina. When this course is very oblique a considerable extent of the spinal nerve may be included within the cavity of the vertebral canal. Particularly striking is the obliquity of course and long intravertebral extent of the lumbar and sacral nerves. Indeed, some of the latter follow almost a vertical course, enveloping the conus medullaris and the filum terminale as a great bundle of nerves known as the horse's tail (*cauda equina*).

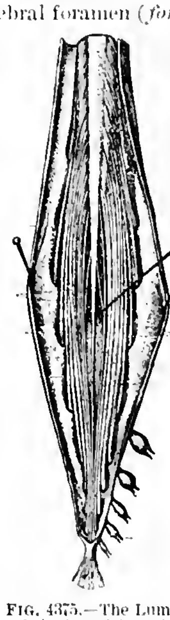

FIG. 4375.—The Lumbar Spinal Cord (pars lumbalis medullæ spinalis) with the terminal cone (conus medullaris), terminal thread (filum terminale), and the horse's tail (cauda equina). Viewed from behind. (After C. Toldt, "Anatomischer Atlas," Wien, 1900.)

There are thirty-one pairs of spinal nerves, connected with the spinal cord. The spinal nerves are named according to their exit from the vertebral canal. The uppermost spinal nerve leaves the vertebral canal between the atlas and the os occipitale. All other spinal nerves come out through the intervertebral foramina between adjacent vertebræ, the lowermost one making its exit through the opening between the first and second por-

* It is customary to find the funiculi of the spinal cord referred to in English text-books as the "columns of white matter" of the cord. It is preferable to retain the term column for the longitudinal strands of *gray* matter, and to use the terms funiculi and fasciculi for the strands of white matter.

tions of the os coccygis. It is customary then to divide the spinal nerves into cervical nerves (*Nn. cervicales*), thoracic nerves (*Nn. thoracales*), lumbar nerves (*Nn. lumbales*), sacral nerves (*Nn. sacrales*), and coccygeal nerve (*N. coccygeus*). There are eight cervical nerves, twelve thoracic nerves, five lumbar nerves, five sacral nerves, and one coccygeal nerve The portion of the spinal cord connected with the cervical nerves is known as the cervical part (*pars cervicalis*). The portion of the cord connected with the thoracic nerves is known as the thoracic part (*pars thoracalis*). The portion of the cord connected with the lumbar and upper sacral nerves is known as the lumbar part (*pars lumbalis*). That portion of the cord which is below the pars lumbalis is called the conus medullaris. The pars cervicalis includes the intumescentia cervicalis; the pars lumbalis includes the intumescentia lumbalis.

Each spinal nerve belongs to one segment of the body (*metamere*). The motor part of each spinal nerve innervates the muscle derived from the muscular part (*myotome*) of a given metamere. The sensory part innervates all of the derivatives of a given metamere supplied with sensory nerves. One spinal nerve, together with its fibres of distribution, its ramus communicans and corresponding portion of the sympathetic, its roots, and the portion of spinal cord belonging to it, makes up the nervous part (*neurotome*) of a given metamere.

If the spinal cord be cut through at different levels (*sectiones medullæ spinalis*), it will be seen to contain a central canal (*canalis centralis*) and to be made up of gray matter (*substantia grisea*) and white matter (*substantia alba*). In general, the white matter is outside and the gray matter inside, and the latter in a transverse section assumes more or less the shape of the letter **H**; but the relations which exist between the white matter and the gray matter vary somewhat at different levels of the spinal cord. It will be convenient, therefore, to study first the topographical appearances of a transverse section through the *middle of the cervical portion of the spinal cord* (Fig. 4376), and afterward to compare with it the topographical appearances met with at other transverse levels.

On each side of the middle line of the cord the structures are almost identical. The anterior median fissure in front and the posterior median sulcus, together with the septum medianum posterius behind, divide the cord almost completely into two symmetrical halves.

The sulcus medianus anterior is broad and deep; as seen in cross-section it extends through about one-third of the depth of the cord. In it is lodged a fold of the pia mater carrying blood-vessels. The shallow sulcus medianus posterior is situated in the middle line behind. Extending from the floor of this sulcus through the white matter as far as the transverse bar of the **H** of gray matter, the septum medianum posterius can be seen. It consists of a condensed mass of certain supporting structures of the cord (ependyma cells).

While the cord is nearly cut in two by the fissura mediana anterior in front and the septum medianum posterius behind, the two halves are really connected by a transverse bar of nerve substance called the commissure. This commissure consists partly of white matter, partly of gray matter. The anterior third is white matter and is called the white anterior commissure (*commissura anterior alba*). The posterior two-thirds consists of gray matter called the gray commissure (*commissura grisea*). In the middle of the commissure is seen the cross-section of the central canal (*canalis centralis*) of the spinal cord, lined by ependymal epithelium, a canal which is continuous above with the ventricles of the brain. The gray matter surrounding it differs from the rest of the gray matter, being somewhat more transparent and reacting in a different way to staining reagents. This special gray matter is called the central gray substance of the spinal cord (*substantia grisea centralis*). It will be noticed that the central canal divides the commissure into an anterior part (*commissura anterior*) and a posterior part (*commissura posterior*). The anterior commissure consists of white matter in front, the anterior white commissure (*commissura anterior alba*), and gray matter behind, the anterior gray commissure (*commissura anterior grisea*). The posterior commissure (*commissura posterior*) consists chiefly of gray matter, though some white fibres run through it. The posterior median septum abuts upon the commissura posterior. The fissura mediana anterior extends in the depth as far as the commissura anterior alba.

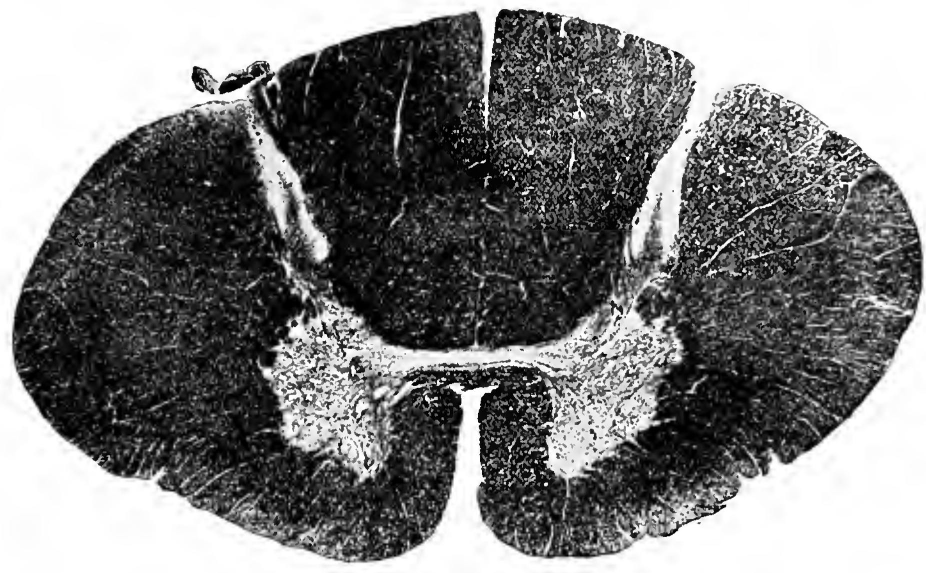

FIG. 4376.—Transverse Section Through the Fourth Cervical Segment of the Human Spinal Cord. (After A. Bruce, "Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

An examination of the distribution of the **H**-shaped mass of gray matter shows that the long lateral limbs of the **H** are directed, generally speaking, from before backward, though they are inclined a little lateralward behind. The gray commissures form the cross bar of the **H**; the lateral limbs of the **H** are not, however, even in thickness, the gray mass being more expanded in its anterior part and more elongated and narrow in its posterior part. On the lateral surface of the gray matter there is a distinct projection of gray matter lateralward into the white matter, to be seen in the cross section. The expanded anterior part of the gray matter is known as the anterior or ventral horn, and since, when the third dimension is considered, it represents a mass extending the whole length of the cord in its anterior part, it is called the anterior column of gray matter of the cord (*columna anterior*). The posterior narrower portion of gray matter is called the posterior or dorsal horn of the gray matter, or posterior column (*columna posterior*). The lateral projection of gray matter is known as the lateral horn, or lateral column (*columna lateralis*) These seen emerging from the area corresponding to the sulcus lateralis anterior. In the cross-section, fibres running out from the anterior horn or anterior column of gray matter can be traced horizontally, or somewhat obliquely,

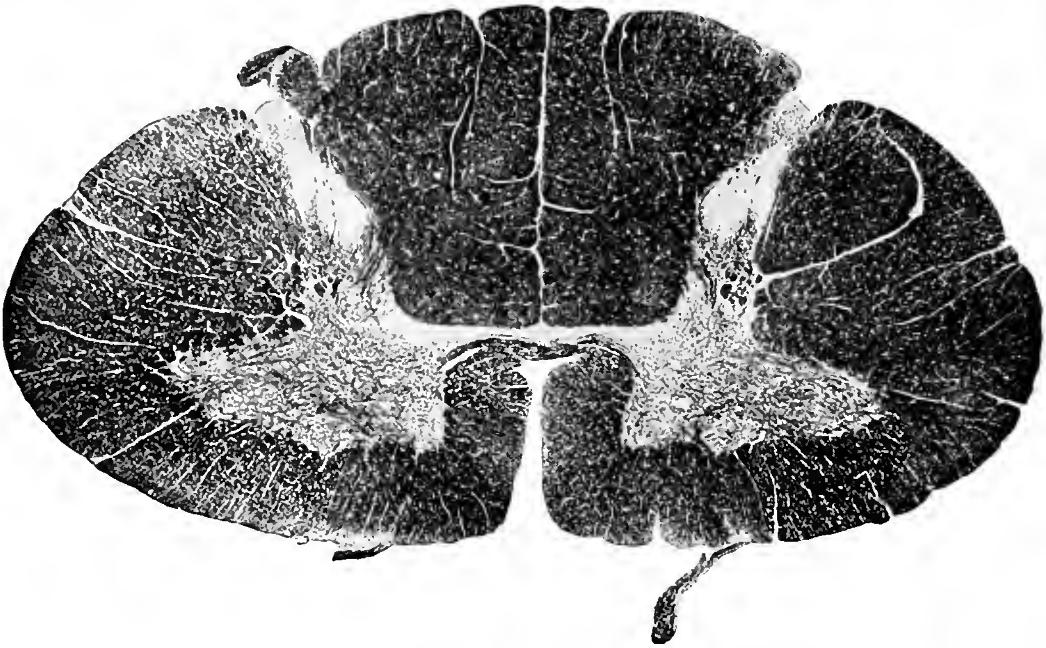

FIG. 4377.—Transverse Section Through the Sixth Cervical Segment of the Human Spinal Cord. Weigert myelin-sheath stain. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

three gray columns (*columnæ griseæ*) on each side, together with the gray commissures, make up the whole extent of the gray matter of the cord, with the exception of a few strands of gray matter which mix in with the white matter in the form of a network at the angle between the lateral column and posterior column of gray matter. This network of gray matter is the so-called reticular formation (*formatio reticularis*). Elsewhere the gray matter is sharply marked off on all sides from the white matter which surrounds it.

The anterior horn, or anterior column of gray matter, is separated from the periphery of the cord by a thick layer of white matter. The posterior horn, or posterior column of gray matter, arrives much nearer to the surface in the region of the sulcus lateralis posterior. It does not, however, reach the surface of the cord, being separated from it by a narrow zone of white matter, known as the fasciculus of Lissauer.

On looking more closely at the posterior horn or posterior column of gray matter, it will be seen to be somewhat constricted in the cross-section, a little behind the gray commissure. This constriction is known as the neck of the posterior column (*cervix columnæ posterioris*). The tip of the posterior column behind is called the apex (*apex columnæ posterioris*). It is sometimes capped, more often crossed, by a somewhat expanded mass of unusually transparent gray matter known as the gelatinous substance of Rolando (*substantia gelatinosa* [*Rolandi*]).

On the surface of the cord the fila radicularia of the radix anterior of the spinal nerve on each side have been through the white matter between the anterior column and the sulcus lateralis anterior. Reaching the surface of the cord they form the fila radicularia of the anterior root.

On the surface of the cord behind, along the sulcus lateralis posterior, the fila radicularia of the posterior root have already been seen. An examination of the sections shows that, on entrance into the cord, the fibres of these fila do not penetrate into the gray matter of the posterior horn, but enter directly the white matter of the funiculus posterior.

FIG. 4378.—Transverse Section Through the Third Thoracic Segment of the Human Spinal Cord. Weigert's myelin stain. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

The subdivision of the white matter in each half of the cord into three funiculi is well shown in the cross-section. The position of the fila radicularia of the anterior roots of the spinal nerves serves to separate the *funiculus*

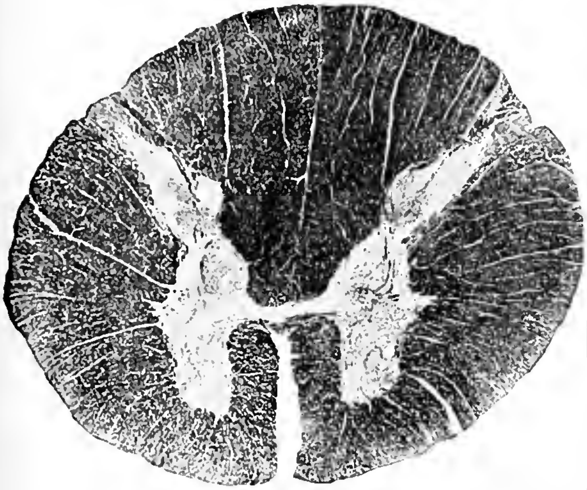

FIG. 4379.—Transverse Section Through the Twelfth Thoracic Segment of the Human Spinal Cord. Weigert's myelin-sheath stain. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

anterior from the *funiculus lateralis* much better than does the shallow sulcus lateralis anterior. Indeed some will have it that no sulcus lateralis anterior exists; it is therefore common to hear the anterior and lateral funiculi grouped together as a single mass of white matter, called the *fasciculus anterolateralis*. The *funiculus posterior* is sharply separated, however, from the funiculus lateralis in the section, by the sulcus lateralis posterior, and in the depth the white masses of the two funiculi are separated from one another by the columna posterior grisea.

The large posterior funiculus, situated between the sulcus lateralis posterior and the sulcus medianus posterior, is subdivided at this level by the sulcus intermedius posterior. Extending into the white substance from this sulcus is a septum of supporting substance known as the *dorsal paramedian septum*. The portion of white matter of the posterior funiculus medial from this septum is called the delicate fasciculus or bundle of Goll (*fasciculus gracilis* [*Golli*]), while the portion laterad from it is known as the wedge-shaped fasciculus or bundle of Burdach (*fasciculus cuneatus* [*Burdachi*]).

The relative distribution of gray and white matter may next be studied in a transverse section, taken at the *level of the sixth cervical nerve*, that is, through the cervical enlargement (*intumescentia cervicalis*) (Fig. 4377). The cord is here seen to be much larger than in the previous section, and the shape of the gray matter is considerably altered. The anterior horn or columna anterior is much larger, and has fused with the lateral horn or columna lateralis so that the latter does not exist at this level as an independent column. The posterior horn or columna posterior of gray matter is a little larger than at the higher level. The formatio reticularis is less pronounced. The frontal diameter of the cord is increased much more than the sagittal. The subdivision of the funiculus posterior into the fasciculus gracilis (Golli) and the fasciculus cuneatus (Burdachi) is still well marked.

At the *level of the third thoracic nerve* (Fig. 4378) the size of the cord has become much reduced, and the sagittal diameter is now much more nearly equal to that of the frontal diameter. The gray matter is present in much smaller amount, the anterior horn or columna anterior has been greatly reduced in size, the lateral horn or columna lateralis is small, and the posterior horn or columna posterior, slender and long. On the medial side of the columna posterior, just in front of its neck in the angle formed by it with the gray commissure, there is an expansion of the gray matter which was not visible in the two sections previously examined. This mass of gray matter contains large cells and is known as the dorsal nucleus of Clarke (*nucleus dorsalis* [*Clarkii*]). It is sometimes known as the column of Clarke or of Stilling. It is present on each side for a long distance in the cord; thus it extends throughout the whole thoracic part of the spinal cord and into the pars cervicalis as far as the level of the eighth or seventh cervical ne. 'e; below, it extends into the pars lumbalis as far as the first or second lumbar nerve. The beginner will find in it a useful landmark for the recognition of sections derived from the pars thoracalis.

The dorsal paramedian septum, separating the fasciculus gracilis from the fasciculus cuneatus, is still present at this level, but it is less distinct than at higher levels, and is placed much nearer the middle line. The fasciculus gracilis is seen to be, accordingly, much smaller in volume than at higher levels. The septum grows less and less distinct as the pars thoracalis is descended, until at about the level of the eighth thoracic nerve it has entirely disappeared and the posterior funiculus is no longer subdivided into two fasciculi.

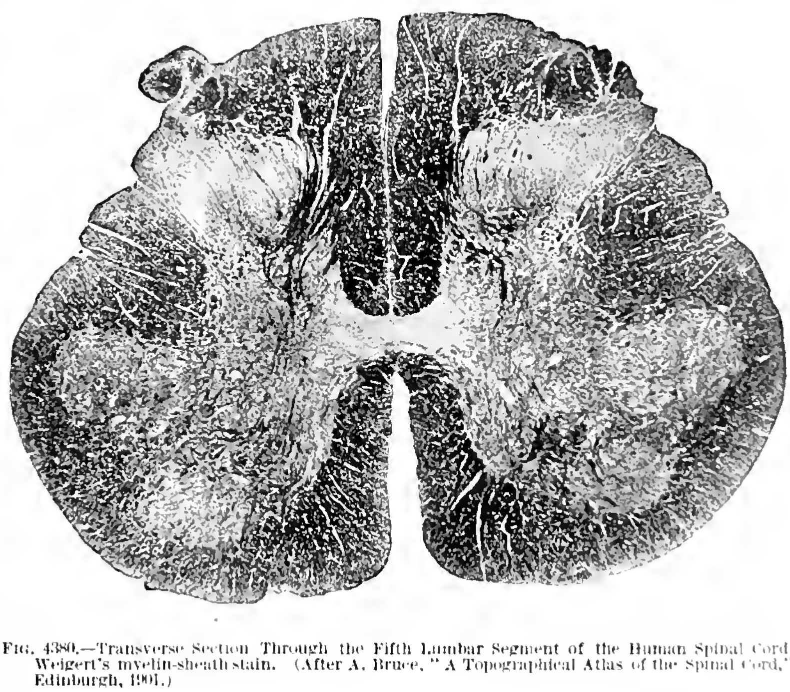

FIG. 4380.—Transverse Section Through the Fifth Lumbar Segment of the Human Spinal Cord. Weigert's myelin-sheath stain. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

Sections of the thoracic cord below the eighth thoracic nerve show no marked alterations in the disposition of the white and gray matter until the lumbar enlargement (*intumescentia lumbalis*) is approached. Then the whole cord grows larger, both the gray matter and the white matter increasing in amount, the gray matter, however, to a greater extent than the white matter.

At the *level of the twelfth thoracic nerve* (Fig. 4379) a transverse section of the cord shows the beginning expansion of the gray matter. The nucleus dorsalis

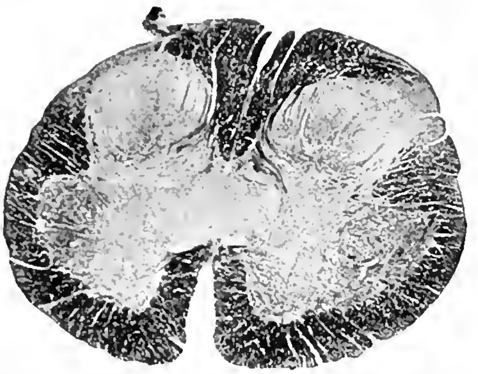

FIG. 4381.—Transverse Section Through the Third Sacral Segment of the Human Spinal Cord. Weigert's myelin-sheath stain. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

(Clarkii) is here very distinct. From this level on, the gray matter increases very rapidly in amount, until the maximum expansion is reached in the largest part of the intumescentia lumbalis.

The relations at the *level of the fifth lumbar nerve* are well shown in Fig. 4380. The anterior and lateral columns of gray matter are again fused and form a much expanded mass in the anterior part of the cord. The posterior column or horn is enlarged to a greater extent here than in any other part of the cord. The enlargement involves especially its medial surface, with the result that the volume of the funiculus posterior of the white matter is relatively small. Indeed, a striking feature of cross sections through the lumbar enlargement is the thinness of the white envelope and the marked expansion of the gray matter. In the latter the substantia gelatinosa (Rolandi) is especially prominent.

In the parts of the cord below the lumbar enlargement this disproportion between the volume of the gray matter and that of the white matter increases. A transverse section at the *level of the third sacral nerve* (Fig. 4381) shows this distinctly, and it is even more marked in a transverse section through the lower part of the conus medullaris at the *level of origin of the N. coccygeus* (Fig. 4382). Here the terminal mass of gray matter is surrounded only by a thin film of white matter. The filum terminale is so atrophic that sections of it reveal only the central canal, lined by ependymal epithelium and surrounded by a thin layer of gray substance, and outside of all the filum duræ matris spinalis.

To the naked eye the white matter of the different funiculi looks very much alike, and cannot be differentiated into the fasciculi, of which, from embryological and pathological studies, we know it to be composed. It will be seen later, however, that the funiculus anterior of the white matter contains the anterior cerebro-spinal fasciculus, or anterior pyramidal tract (*fasciculus cerebrospinalis anterior*) and the so-called ground bundle of the anterior funiculus (*fasciculus anterior proprius*). The funiculus lateralis of the white matter contains the lateral cerebro-spinal fasciculus or lateral pyramidal tract (*fasciculus cerebrospinalis lateralis*), the direct cerebellar tract (*fasciculus cerebellospinalis*), Gowers' tract (*fasciculus anterolateralis superficialis*), and the lateral ground bundle (*fasciculus lateralis proprius*). The funiculus posterior of the white matter contains the tracts of Goll and Burdach (*fasciculus gracilis Golli et fasciculus cuneatus [Burdachi]*). The exact location of these various fasciculi and the mode of determining their location will be described farther on in this article.

The Coverings of the Cord (*Meninges*).—The spinal cord is surrounded in the vertebral canal by three membranes known as the spinal meninges; they are continuous above with the cerebral meninges. These three membranes are known as the *dura mater spinalis*, the *arachnoidea spinalis*, and the *pia mater spinalis*.

The dura mater is the strongest of the three and most external. The pia mater is the most delicate and the most internal, being applied everywhere closely to the cord. Between the two is the delicate non-vascular arachnoid. Between the dura mater and the inner surface of the bony vertebral canal is a cavity known as the epidural cavity (*cavum epidurale*). Between the dura mater and the arachnoid is a space called the subdural cavity (*cavum subdurale*). More important, however, is the space between the arachnoid and the pia mater. This is the subarachnoid cavity (*cavum subarachnoideale*); it contains the cerebro-spinal fluid (*liquor cerebrospinalis*).

The spinal dura mater (*dura mater spinalis*) extends from the foramen magnum to the level of the second or third sacral vertebra. It differs from the dura mater of the brain in that it splits into two layers, the outer one becoming continuous with the periosteum and ligaments of the vertebral canal, and the inner one forming the dura mater spinalis proper. The latter layer is the one usually referred to when the spinal dura mater is spoken of, but it must be remembered that the outer layer must be added to it to make it homologous with the dura mater encephali. In the space between the outer layer and the dura mater spinalis proper, that is in the cavum epidurale, there are besides fatty tissue and some plexuses of veins and lymph channels. The thickness of the dura mater spinalis in the adult averages 0.5–0.6 mm.

Some fibrous filaments from the anterior middle line of the dura run obliquely downward and ventralward to be inserted into the posterior longitudinal ligament of the spine. These are especially developed from the fourth lumbar vertebra downward, where they fuse to form a membrane, the so-called anterior sacrodural ligament (*ligamentum sacrodurale anterius*).

The spinal dura mater forms a separate sheath for each of the two roots, the anterior root and the posterior root, of each spinal nerve. These sheaths are continued upon the roots as far as the spinal ganglia, where they become lost in the connective tissue of the peripheral nerves and in the periosteum of the bones.

At its lower extremity the dura mater spinalis forms a sac which envelops the nerve roots of the cauda equina. This sac terminates at the level of the second or third sacral vertebra, but the dura mater is continued as a sheath closely applied to the filum terminale. This portion of it, a long, tough thread, called the filum duræ matris spinalis, is finally inserted upon the posterior surface of the os coccygis.

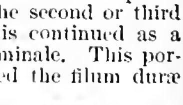

FIG. 4382.—Transverse Section Through the Coccygeal Segment of the Human Spinal Cord. Weigert's myelin-sheath stain. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.)

The dura mater spinalis is connected with the arachnoidea by means of the so-called subdural threads and with the pia mater by the denticulate ligament (*ligamentum denticulatum*). The subdural threads are very fine and short, are connected with the outer surface of the arachnoidea, and usually carry blood-vessels. The ligamentum denticulatum is a membrane stretched out in a frontal or coronal plane between the dura mater and the pia mater, just midway between the anterior and posterior surfaces of the cord; it passes between the anterior and posterior roots of the spinal nerves. Its medial border is firmly attached to the pia mater. Its lateral border is toothed, the teeth being inserted at their summits into the dura mater midway between the exits of adjacent spinal nerves. Intermediate between the teeth the lateral edge of the membrane forms free arcades. The number of teeth varies from eighteen to twenty-three. In the cervical region the N. accessorius runs behind the ligament.

The spinal arachnoid (*arachnoidea spinalis*) bounds the subdural cavity internally. It is to be noted that this is what is called by many anatomists the "visceral layer of the arachnoid"; below, it is reflected at the tip of the conus terminalis upon the dura mater to form the "parietal layer of the arachnoid" of various authors. This is why some writers call the cavum subdurale, situated between the parietal layer and the visceral layer of the arachnoid, the "arachnoid cavity." It is a serous cavity, like the pleura.

The arachnoid contains no blood-vessels; occasionally calcified plates are found in the membrane. The arachnoid is prolonged over the nerve roots, and over the summits of the teeth of the ligamentum denticulatum.

As a rule, it is very difficult to separate the arachnoid from the pia mater macroscopically. Key and Retzius describe the two together as the "meninx tenuis." These soft membranes, together, are also designated, the "leptomeninges," to distinguish them from the hard or tough membrane, the dura mater or "pachymeninx." If the visceral layer of the arachnoid be lifted carefully in the region of the cauda equina and cut through with fine scissors and then split longitudinally upward a little to one side of the median line, the space between the arachnoid and the pia mater, the subarachnoid cavity (*cavum subarachnoideale*), will be exposed. This space is not a free cavity, but really a communicating network of cavities, the walls of which are formed by delicate processes which extend between the arachnoidea and the pia mater. The meshes are filled with cerebro-spinal fluid. It is this cavum subarachnoideale which is tapped in Quincke's lumbar puncture when the needle is introduced opposite the interspace between the third and fourth lumbar vertebræ.

The spinal pia mater (*pia mater spinalis*), a very delicate membrane, closely envelops the spinal cord. It sends a fold into the depth of the fissura mediana anterior and elsewhere is intimately adherent to the external surface of the cord. It is extremely rich in blood-vessels, for it is in this membrane that the arteries which supply the cord undergo multiple subdivision before penetrating into the substance of the cord. When the pia mater is pulled off the cord, a number of minute arteries and capillaries are always torn out of the white substance; many of these are so small, however, that they cannot be made out with the naked eye.

The Blood-Vessels of the Spinal Cord (Fig. 4383).—The arterial supply of the spinal cord is derived from the vertebral arteries (*rami spinales Aa. vertebrales*), the ascending cervical arteries (*rami spinales Aa. cervicales ascendentes*), the posterior rami of the intercostal arteries (*rami spinales Rr. post. Aa. intercostales*), the posterior rami of the lumbar arteries (*rami spinales Rr. post. Aa. lumbales*), the ilio-lumbar arteries (*rami spinales Aa. iliolumbales*), and the lateral sacral arteries (*rami spinales Aa. sacrales laterales*).

Besides the rami spinales given off from the cervical portion of the A. vertebralis which pass through the foramina intervertebralia, each vertebral artery gives off an anterior spinal artery (*arteria spinalis anterior*) (O. T. A. vertebrospinalis anterior), and a posterior spinal artery (*A. spinalis posterior*) (O. T. A. vertebrospinalis posterior). The anterior spinal arteries of the two sides run medialward and caudalward and unite near the fissura mediana anterior somewhere between the foramen magnum and the level of the third cervical nerve. The trunk resulting from the fusion of the two, sometimes called the median anterior vertebro-spinal artery (*A. vertebrospinalis anterior mediana*), runs downward, unpaired on the anterior surface of the cord (not in the anterior median fissure), as far as the level of the fourth or fifth cervical nerve, where it ends by fusing with the *tractus arteriosus*

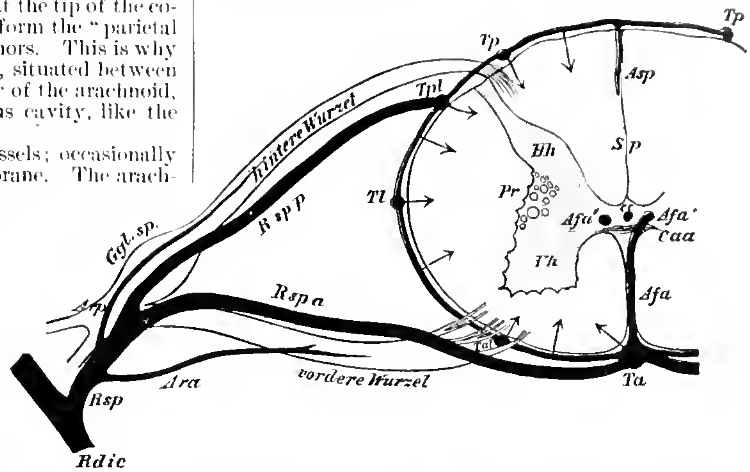

FIG. 4383.—Schematic Representation of the Arterial Vessels of a Segment of the Spinal Cord. For the sake of clearness the relative size relations of the vessels have been incorrectly drawn. *Afa*, Arteria fissuræ anterioris; *Afa'*, longitudinal central branch (ascending or descending) of *Afa*; *Afa"*, longitudinal central branch of the *Afa* next above or next below; *Ara*, arteria radicina anterior; *Arp*, arteria radicina posterior; *Asp*, arteria septi mediana posterior; *Caa*, commissura anterior alba; *Ce*, canalis centralis; *Ggl.sp.*, ganglion spinale; *Hh*, posterior horn of columna grisea posterior; *Vh*, anterior horn or columna grisea anterior; *Pr*, processus reticularis; *Rdic*, rhombus dorsalis seu posterior arteriæ intercostales; *Rsp*, ramus spinalis; *Rspa*, *Rspp*, ramus spinalis anterior, posterior; *Sp*, septum medianum posterius; *Ta*, *Tal*, *Tp*, *Tpl*, tractus arteriosus anterior, anterolateralis, lateralis, posterior, posterolateralis; *hintere Wurzel*, posterior root; *vordere Wurzel*, anterior root. (After T. Ziehen, in Bardeleben's "Handbuch der Anatomie des Menschen," Jena, 1899.)

spinalis anterior, the unpaired anterior median trunk resulting from anastomoses between the various spinal rami which come to the cord at the levels of the nerve roots all the way down as far as the filum terminale.

The posterior spinal artery given off by the vertebral artery is delicate, bends around the lateral margin of the medulla oblongata and runs downward near the nervus accessorius on each side. Having reached the level of the fourth or fifth cervical nerve, it fuses with the longitudinal trunk, known as the *tractus arteriosus posterolateralis*. The latter is made up of ascending and descending branches of the spinal rami of the A. vertebralis, Aa. intercostales, lumbales, iliolumbales, and sacrales laterales.

Besides this tractus arteriosus posterolateralis the posterior spinal artery from the vertebral gives off segmental branches, the so-called penetrating arteries (*Aa. penetrantes*), which, passing medialward and joining with branches of the Aa. intercostales, give rise to another longitudinal trunk called the *tractus arteriosus spinalis posterior*. The latter does not run in the middle line, but runs lengthwise of the cord just behind the line of entrance of the posterior roots. The tractus arteriosus posterolateralis, on the other hand, runs anterior to and lateralward from the sulcus lateralis posterior or line of entrance of the posterior roots.

The rami spinales of the rami posteriores of the Aa. intercostales, the rami spinales of the Aa. lumbales, the A. iliolumbalis, the A. sacralis lateralis, as well as of the A. cervicis ascendens all run through the intervertebral foramina. On passing through the foramen, each ramus spinalis gives off two delicate branches, one to the anterior root (*A. radicina anterior*), the other to the posterior root (*A. radicina posterior*), and then, near the spinal ganglion, usually divides into two branches, one going to the front of the cord (*ramus spinalis anterior*), the other going to the postero-lateral surface of the cord (*ramus spinalis posterior*). It is to be noted that there is not a ramus spinalis for every nerve-root level; and further, that sometimes when a ramus spinalis is present, it does not divide into two branches but becomes entirely an anterior ramus or a posterior ramus, more often the latter. Thus, according to Kadyi, there are, as a rule, eight large rami spinales anteriores and as many as sixteen or seventeen rami spinales posteriores. Among the rami spinales anteriores there is usually one which is much larger than the others; this is sometimes called the *A. magna spinalis*, or *A. radicalis magna*. It may be either on the left side or on the right side, and is most often found in the lower thoracic region at the level of the ninth, tenth, or eleventh thoracic nerve. These anterior spinal rami run medialward as far as the fissura mediana anterior, and there divide into an ascending and a descending ramus. These ascending and descending rami fuse with those of adjacent levels, thus helping to form the general *tractus arteriosus spinalis anterior* of Kadyi, which lies in the epipial areolar tissue in the cavum subarachnoideale.

The posterior spinal rami run also medialward to the surface of the cord, just in front of the line of entrance of the posterior roots, and like the anterior spinal rami also divide into ascending and descending limbs, which, anastomosing with corresponding limbs of rami of adjacent levels, give rise to the longitudinal trunk known as the *tractus arteriosus posterolateralis*. Other rami spinales posteriores run farther backward and medialward, pass between the posterior roots of different levels, or among the fila radicularia of the posterior roots to reach a position just medial from the sulcus lateralis posterior, where they divide into ascending and descending limbs, which contribute to another longitudinal anastomosis known as the *tractus arteriosus posterior*, to which the Aa. penetrantes from the A. spinalis posterior of the A. vertebralis has above been seen to contribute.

The tractus arteriosus posterolateralis lies lateral from the posterior root and outside the pia mater. The tractus arteriosus posterior lies medial from the posterior root, but inside the pia mater. Between the tractus arteriosus posterior of one side and its fellow on the opposite side pass transverse anastomoses like the rungs of a rope ladder. These transverse rami are particularly noticeable opposite the cervical and lumbar enlargements.

About one-half a centimetre above the tip of the conus medullaris a large transverse anastomosing branch can be seen, connecting the tractus arteriosus posterolateralis with the tractus arteriosus anterior. The presence of this large branch, sometimes called the *ramus cruciens*, explains why it is that fluid injected through the arteria spinalis magna may be distributed through the blood vascular network of the whole lower half of the cord on its posterior surface.

The anterior spinal artery and the tractus arteriosus spinalis anterior with which it is continuous give off two sets of branches. One set is central (*Aa. fissurales anteriores seu centrales*); the other set is lateral and peripheral (*rami laterales*).

The anterior fissural arteries (*Aa. fissurales anteriores seu centrales*), two hundred to two hundred and sixty in number, pass into the depth of the anterior median fissure and divide into two branches, one of the latter passing to the right, the other to the left. These branches go through the commissura anterior alba to the gray substance. They are known as the sulco-commissural arteries (*Aa. sulcocommissurales*). They often divide into ascending and descending branches which supply the whole of the gray matter of both the anterior and posterior horns, with the exception of the most peripheral part of the gray substance next to the white matter. The special branches going to the nucleus dorsalis are called the *arteriolæ columnarum Clarkii*.

The rami laterales go to the anterior roots and anastomose with the Aa. radicinæ anteriores; sometimes they form a longitudinal anastomotic chain called the *tractus arteriosus anterolateralis*. Other branches run backward to meet branches running forward from the tractus arteriosus posterolateralis and to form a lateral longitudinal anastomosis known as the *tractus arteriosus lateralis*.

The whole of the white matter and the most peripheral part of the gray matter get their blood supply from branches penetrating the cord from the tractus arteriosus anterolateralis, tractus lateralis, tractus posterolateralis, tractus posterior, and the Aa. radicinæ anteriores et posteriores. All these vessels have been grouped together by Adamkiewicz, under the name vasocorona.

From the transverse anastomoses between the tractus arteriosi posteriores of the two sides, certain unpaired posterior sulcal arteries (Aa. sulcales posteriores) penetrate into the cord in the region of the sulcus medianus posterior. These are much branched and supply the white substance, but scarcely go so deep as the posterior commissure. Branches from them may, however, reach the posterior horn or the nucleus dorsalis, and help to contribute to the blood supply of those parts. Minute vessels, entering the white substance between the fasciculus gracilis (Golli) and the fasciculus cuneatus (Burdachi), tolerably constant in the upper portions of the cord, have been called the interfunicular arteries (*Aa. interfuniculares*). The branches of the Aa. radicinæ posteriores et anteriores which reach the interior of the cord are small, but they play some part in the vascularization of the anterior and posterior horns of gray matter.

The arteries supplying the spinal cord are *end arteries* in the sense of Cohnheim. This is true of all the branches going in from the vasocorona as well as of the branches of the Aa. sulcales anteriores et posteriores. This explains the possibility of minute infarctions in the spinal cord. Despite the manifold longitudinal anastomoses throughout the whole length of the cord between the arteries of all levels, the cutting off of the blood supply through the lumbar and sacral vessels leads irrevocably to the death of the gray matter of the lower part of the cord, as has been over and again demonstrated by the experiment in which the abdominal aorta is compressed for half an hour.

The capillaries of the cord empty into the veins which form a network in the pia. Out of this network several large veins become differentiated, and these have been given special names. Thus, on the anterior surface of the cord are found: (1) *V. spinalis mediana anterior*; (2) *V. spinalis lateralis anterior dextra*; (3) *V. spinalis lateralis anterior sinistra*. On the posterior surface of the cord a median and two lateral veins can also be made out: (1) *V. spinalis mediana posterior*; (2) *V. spinalis lateralis posterior dextra*; and (3) *V. spinalis lateralis posterior sinistra*.

All these veins are devoid of valves. They empty through the *Vv. spinales anteriores et posteriores* largely into the *plexus venosi vertebrales interni*, and partly through the *Vv. intercostales* into the *V. azygos*. Some of the veins pass by way of the *Vv. lumbales* into the V. cava inferior. Other veins go by way of the *V. iliolumbalis* and the *Vv. sacrales laterales* into the V. hypogastrica, and so through the V. iliaca communis into the V. cava inferior.

The veins from the gray matter empty largely through the *Vv. fissurales anteriores* into the V. spinalis mediana anterior.

On Some Macroscopic Details

Upper and Lower Limits of Cord.—The upper limit of the spinal cord in man and mammals corresponds to the lateral exit of the uppermost fila radicularia of the first cervical nerve. This point corresponds ventralward to the lowermost bundles of the decussatio pyramidum. The lower level of the cord, that is its junction with the filum terminale, nearly always lies on a level corresponding to the lower third of the first lumbar vertebra or the upper third of the second lumbar vertebra, though in forty per cent. of the cases it may lie opposite the upper two thirds of the first lumbar or the lower two-thirds of the second lumbar vertebra. In one case it ended 5 mm. above the lower border of the twelfth thoracic vertebra, and it has been found as far down as the lower margin of the second lumbar vertebra. (See report of Committee of Collective Investigation of Anatomical Society of Great Britain and Ireland for the year 1893–94, *Jour. Anat. and Physiol.*, vol. xxix., 1895, pp. 35–60.)

Length of Spinal Cord.—The extreme variations in the male are 44–50.6 cm.; in the female, between 39 and 47 cm. As to the relation of the length of the cord and the length of the vertebral column, measured from the foramen magnum to the basis ossis sacri, it may be stated that when the average length of the spinal column is designated 100, the length of the male spinal cord will be 64, that of the female spinal cord about the same. The average length of the vertebral column in the male is 70 cm.; in the female, 68 cm. (Ziehen).

Frontal and Sagittal Diameters.—The minimum measurements are met with in the middle of the thoracic cord, where the sagittal diameter measures about 8 mm., the frontal diameter about 10 mm. The maximum measurements in the intumescentia cervicalis are met with opposite the fifth or sixth cervical vertebra, where the sagittal diameter is 9 mm., the frontal diameter 13–14 mm. The maximum measurements in the lumbar enlargement are met with opposite the twelfth thoracic vertebra, where the sagittal diameter is about 8.5 mm., the frontal diameter 11–13 mm.

Upper Level of Conus Medullaris.—Charpy designates as the arbitrary upper limit of the conus medullaris a plane lying between the exit of the fifth sacral nerve and the nervus coccygeus. According to this the conus medullaris would measure about 10 mm. in length. Raymond states that clinicians usually regard the conus medullaris as extending farther up, usually to the plane between the third and fourth sacral nerve roots. This would make the conus medullaris considerably longer.

Swellings Other Than the Cervical and Lumbar Enlargements.—The segmental swellings observable in animals and corresponding to the origins of the nerve roots, despite the assertions of some authors, are not observable in the human spinal cord. Two slight enlargements, however, are to be made out in the human conus medullaris and filum terminale. One is situated at the region of transition of the conus medullaris into the filum terminale and corresponds to the ventriculus terminalis; the other enlargement is situated about 1 cm. farther caudalward.

Weight of Spinal Cord.—The average weight has been given above. The weighings of Meckel are of interest. For the three-months' fœtus, 0.12 gm. (= $\frac{1}{8}$ of brain weight); for the five-months' fœtus, 0.36 gm. (= $\frac{1}{63}$ of brain weight); for the nine-months' fœtus, 2.7 gm. (= $\frac{1}{107}$ of brain weight); for a five-months' child, 5.4 gm.

The relative weight of the human spinal cord compared with the body weight is as 1:1849.5 in the adult; in the new-born as 1:851.4. The relation of the human spinal-cord weight to body weight in a whole series of animals is given in Ziehen (*loc. cit.*). Keith has made many such measurements. Ziehen also gives a long table in which the relative weight of the spinal cord to the brain weight in animals is given. It is smallest in man and increases in the animal series steadily downward until fish are reached. In the adult human being the relation has been variously estimated from as 1:19 to as 1:51.13. The latest figures are those of Mies, who gives the relative weight of the cord to the brain as 1:49.80 in the female and 1:51.13 in the male.

Relation of Individual Spinal-Cord Segments (*Root Levels*) *to Spinous Processes.*—A number of researches dealing with the problem are available. In general it may be said that in the cervical region of the vertebral column the ordinal numeral of the spinous process is to be increased by one in order to give the ordinal numeral of the cervical nerve root arising at the level of that spinous process. In the region of the thoracic vertebræ two is to be added to the number of the spinous process in the upper half, while from the sixth to the eleventh thoracic vertebræ one must add three. The lower part of the spinous process of the eleventh thoracic vertebra and the interspace between this spine and the next lower corresponds to the origin of the third to the fifth lumbar roots; the spinous process of the twelfth thoracic vertebra and the interspace between it and the spinous process of the first lumbar vertebra correspond to the origin of the sacral roots. It is to be remembered that when the trunk is strongly flexed, the spinal cord with attached nerve roots is displaced a few millimetres upward.

The levels of the nerve roots differ somewhat in the child from those in the adult, as Chipault has pointed out. Thus in children under seven years of age we add three to the ordinal numeral for the spinous process in the region of the first four thoracic vertebræ to get the number of the nerve root of corresponding level; and in the region of the fifth to ninth thoracic vertebræ four must be added.

The lower level of the dural sac in the adult corresponds about to the level of the spinous process of the first sacral vertebra.

The topographical relations between the spinous processes and the roots of the spinal nerves are well shown in the accompanying figure copied from Reid (Fig. 4384).

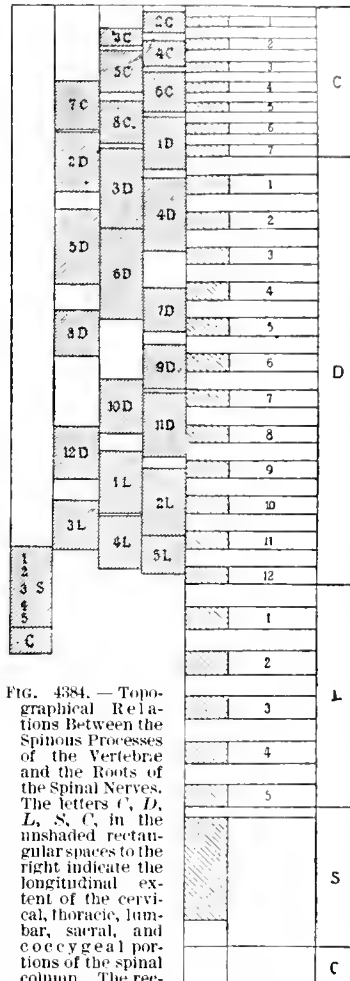

FIG. 4384. — Topographical Relations Between the Spinous Processes of the Vertebræ and the Roots of the Spinal Nerves. The letters *C, D, L, S, C*, in the unshaded rectangular spaces to the right indicate the longitudinal extent of the cervical, thoracic, lumbar, sacral, and coccygeal portions of the spinal column. The rectangular spaces shaded obliquely from the left and above downward and to the right indicate the longitudinal extent of the spinous processes of the individual vertebræ, while the rectangular spaces shaded obliquely from the right and above downward and to the left, indicate the region within which the origin of the individual roots of the spinal nerves is to be sought. The horizontal extent of the rectangular space has no significance. (After Reid, *Journ. Anat. and Physiol.*, Lond., 1889, p. 341.)

Cauda Equina.—Exact measurements have been made in an eighteen-year old individual of the distances between the root origins of the lumbar and sacral nerves and their foramina intervertebralia of exit by Testut. The distances measured are as follows:

N. lumbalis I........	114 mm.	N. lumbalis V.......	181 mm.
N. lumbalis II.......	138 "	N. sacralis I.........	188 "
N. lumbalis III......	151 "	N. sacralis V..	280 "
N. lumbalis IV......	163 "		

The filum terminale measures 16 cm. in length and extends from the third lumbar vertebra to the second coccygeal vertebra.

Length of Different Portions of the Cord.—Ravenel (*loc. cit.*) gives the following measurements:

	In the male.	In the female.
Pars cervicalis	9.9 cm.	9.6 cm.
Pars thoracalis	26.2 "	22.9 "
Pars abdominalis	5.1 "	5.7 "
Pars pelvina	3.6 "	3.1 "

The thirty-one segments corresponding to the thirty-one pairs of nerve roots have been carefully measured in six individuals by Lüderitz (for the figures his original article is referred to). The longest segment is found about the middle of the pars thoracalis and corresponds to the fifth, sixth, seventh, or eighth N. thoracalis. The shortest segment usually pertains to one of the lowermost Nn. sacrales. The difference in length of segments is dependent upon growth relations. The length of the segments increases steadily from the lower part of the sacral cord up to the middle of the pars thoracalis, the increase being at first slight, between the individual segments, but higher up it is greater. The length of the segments then diminishes until the lowermost portion of the pars cervicalis is reached. In the latter the segments measure about alike, though there are slight variations.

Number of Spinal Nerves.—Thirty one pairs of spinal nerves are usually described for human beings, though Rauber has demonstrated traces of a second and third coccygeal nerve lying close upon the filum terminale. Occasionally a sixth pair of sacral nerves is present when there are more sacral vertebræ than normal. Single thoracic nerves may be absent (Adamkiewicz).

Topographical Relations of Gray Matter and White Matter.—A most valuable contribution to our knowledge of the details of these relations is to be found in Bruce's "Atlas of the Human Spinal Cord." It includes photographs of transverse sections through every segment of the cord. It is of the greatest convenience in helping to localize the origin of transverse sections of the human cord of unknown level.

Exact measurements of the surface amounts of the white and gray substances at different levels of the cord have been made by Stilling, who even went so far as to measure the surface areas of the individual funiculi at nearly all levels of the cord. Stilling's book on the spinal cord is a mine of valuable statistics.

In Stilling's book (1859) there are data concerning the areas of white and gray substance in cross-sections of the spinal cord of a child of five years, and these data were later used by Woroschiloff (1874) for the construction of curves. His curves are those at present employed in most text-books, too often without any accompanying statement to show that they are based on the measurement from an immature cord. Another point to be borne in mind in dealing with curves representing the true relations between the gray and the white matter is this, that the segments of the cord should be represented in their true length. The curves worked out by Krause and Aguerre would have been more valuable had they paid attention to the lengths of the segments.

Donaldson and Davis, of the University of Chicago, have recently constructed curves in which not only the area of the entire section, but also those of the white matter and the gray matter separately are represented, and in which the age of the individual and the true lengths of the individual segments of the spinal cord have been regarded. The accompanying charts make clear at a glance the results obtained (Fig. 4385). Donaldson and Davis find that the form of the cord from one to five years is nearly like that of maturity, the difference being that in the mature cord the relative enlargement of the areas of the cross-sections has become greater in the thoracic region, but less in the sacral and coccygeal. At maturity the relative enlargement of the two intumescentiæ is practically the same as at the fifth year. From the fifth year to maturity both the length and the weight of the entire cord, as well as the area of the cross-sections at the level of the several segments, are increased. The sum of the areas of the white substance at maturity is ninety-eight per cent. greater than at five years, and that of the gray substance twenty-three per cent. greater. This absolute increase must represent either enlargement of elements

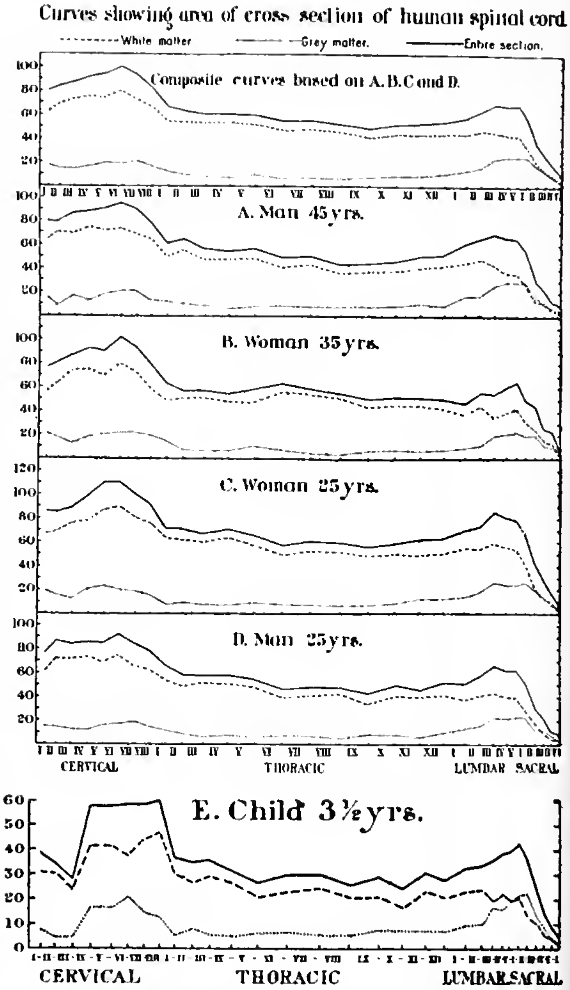

FIG. 4385.—This chart represents, by curves, the areas of the cross-sections of several human spinal cords, as well as the areas of the gray and white substances as they appear in each section. The base line in all the charts is just one-third the length of the spinal cord for which it stands, and is divided into lengths proportional to those of the spinal-cord segments of which it is composed. For the adult cord, the lengths of the segments given in the first table of the series were used in making the original drawings. On the ordinates one linear millimetre corresponds to one square millimetre of area. In all cases the measurement of the area was made up at the caudal end of the segment. In the order from above downward, the curves are as follows:

Composite Curve. Based on *A*, *B*, *C*, and *D*, to give the average of the several areas in the curves named. The curves are generalized and apply to a cord of medium length—44.6 cm. long. The influence of sex is neglected. The average age of the four cases would be thirty-three years. *Curve A*, Man of forty-five years; data for areas from Stilling. *Curve B*, Woman of thirty-five years; data for areas from Stilling. *Curve C*, Woman of twenty-five years; data for areas from Stilling. *Curve D*, Man of twenty-five years; data for areas from Stilling. *Curve E*, Child—data for areas from Stilling's observations on the cord of the two-year-old child. Length of segments from Lüderitz's observations on the cord of a three-and-a-half-year-old girl. Cord rather short. (After Donaldson and Davis.)

already completely developed or the development of elements still immature at the earlier age, or some combination of both of these processes. Yet the failure of the intumescentiæ to increase in their relative area in the mature cord or in their proportional length would seem to indicate that during this period there was no increase in their relative complexity, a result which, to say the least, was unexpected.

Central Canal.—This is very often invisible in the adult. Its lumen may vanish for considerable distances. It is stated that the central canal may remain open in perhaps ten per cent. of the cases throughout its whole length. Headward it is continuous with the central canal of the medulla oblongata (fourth ventricle), while caudalward it can be followed as far as the middle of the filum terminale, where it ends blindly.

The form of the canal is usually circular or elliptical; in the latter case the longer diameter is most often sagittal. In the intumescentia cervicalis it is a transverse ellipse, and in the intumescentia lumbalis a dorso-ventral ellipse.

The gray matter about it has a gelatinous appearance (substantia gelatinosa centralis) and is rich in neuroglia and derivatives of ependymal cells.

The expansion of the central canal, known as the ventriculus terminalis, lies so near the posterior surface of the cord that some authors have assumed that it opens into the sulcus medianus posterior. No such communication, however, exists.

Heterotopias of the Gray Matter.—Most of the so-called heterotopias or displacements of the gray matter, like many of the so-called doublings of the gray matter and of the cord, have doubtless been due to artefacts produced by violence on removal of the cord. The subject has been thoroughly discussed by van Gieson, who gives credence to a true heterotopia in only a very few of the published cases.

Glial Sheath and Glial Septa.—The thin layer of glia just outside the substantia alba, much thicker in some parts of the periphery than in others, is known as the glial sheath (*Gliahülle* of the Germans). Running in from this glial sheath through the white matter to the gray matter can be seen various glial septa. An excellent description of the distribution of these glial septa is to be found in Ziehen's article on the "Nervous System," in Bardeleben's "Handbook," pp. 57–62.

Microscopic Anatomy of the Spinal Cord.

We have now completed the description of the grosser anatomy of the cord, and shall next pass on to an account of the microscopic appearances. The anterior and posterior roots will first be described, then the white matter of the cord, and lastly, the gray matter. A description of the appearances as met with in ordinary sections will be given first, and afterward the special facts brought to light by special methods will be detailed. In what follows, the reader is expected to have some familiarity with the histology of nerve cells and nerve fibres, to know what is meant by a neurone, to understand the terms dendrites, axone, collaterals, telodendrion, perikaryon, etc. A brief account of all these features will be found in this Handbook under *Brain, Histology of*, Vol. II., pp. 331–344. A reader approaching the microscopic anatomy of the spinal cord for the first time would do well to read this section before going further.

The Anterior Roots.—The exit of the fila radicularia at the sulcus lateralis anterior has already been described. A cross-section of an anterior nerve root shows that it consists almost entirely of medullated nerve fibres, all of which represent axones of lower motor neurones, the cell bodies or perikaryons of which are situated in the columna anterior grisea or anterior horn, of the same side of the spinal cord. Generally speaking, the calibre of the nerve fibre of the anterior root exceeds that of the nerve fibre of the posterior roots. This is especially true of the anterior roots of the Nn. cervicales, Nn. lumbales, and upper Nn. sacrales, where fine fibres occur only singly in the anterior roots. On the other hand, in the anterior roots of the Nn. thoracales and lower Nn. sacrales there are numerous fibres of fine calibre often arranged in groups in among the larger fibres. The fibres of the anterior roots of the cervical nerves vary from 1.3 μ to 23.9 μ. Over half the fibres of these roots have a calibre of from 13.3 μ to 16 μ. The large fibres predominate in the lumbar region, where one-half of all the fibres measure from 21.3 to 23.9 μ (Siemerling). If fibres of more than 5 μ are called *coarse*, and fibres of smaller size are called *fine*, there are five times as many coarse as fine fibres in the anterior roots of the cervical nerves; three times as many fine as coarse in the anterior roots of the thoracic nerves; six times as many coarse as fine in the lumbar roots; four times as many coarse as fine in the sacral roots; and three times as many fine as coarse in the coccygeal nerve root. According to Schwabel the greater the length of a nerve, the larger the calibre of its root fibres, a conclusion which he drew largely from the predominance of the coarser fibres in the cervical and lumbo-sacral roots.

The total number of anterior root fibres in a woman twenty-six years old was found by Stilling to be 303,265. The older counts of Birge in the frog have been extended through the researches of Hardesty. For the details the original article of the latter may be consulted.

The fibres of the anterior roots are surrounded by a myelin sheath before they leave the cord, but only from the point where they leave the pia are they surrounded by a neurilemma and by the connective-tissue sheath, sometimes called the sheath of Henle.

Single nerve cells or small groups of ganglion cells have been observed occasionally outside the spinal cord among the fibres of the fila radicularia of an anterior root. His and Dohrn demonstrated that some neuroblasts could, in the embryo, pass through the marginal veil and get out into the anterior roots. Whether the nerve cells which have been observed in these roots in the adult are derivatives of neuroblasts from the anterior horns, or are dislocated spinal ganglion cells or sympathetic ganglion cells, has not yet been decided. Islands of glia cells have been seen among the anterior roots (Petrone) and the peculiar plaques observed by Hoche in anterior roots may be glial in nature. Ziehen suggests that they are to be looked upon as cone-like dislocations of the glial sheath of the spinal cord.

The Posterior Roots.—In general the fibres of the posterior roots represent the central axones of the peripheral sensory neurones, the cell bodies or perikaryons of which are situated within the spinal ganglion. The fibres of the posterior roots are in general of finer calibre than those of the anterior roots, though the actual measurements vary between 1.3 and 23.9 μ; the same extremes are noted for the anterior roots (Siemerling). In the cervical posterior roots three-quarters of all the fibres have a calibre varying between 8 and 13.3 μ. In the thoracic posterior roots, two-thirds of all the fibres measure 13.3 μ or more. In the lumbar roots a fifth of all the fibres measure 21.3 μ, about one-quarter of them 18.6 μ, and still another quarter 16 μ. The proportion of fine fibres to coarse fibres in the cervical roots is as 21:20; in the thoracic roots as 7:5; in the lumbar roots as 8:9; in the sacral roots as 4:3; and in the coccygeal root as 17:14. The posterior root bundles are somewhat constricted at the point where they pass through the pia and enter the glial sheath of the cord. According to a much considered theory, proliferation of the connective tissue at this spot with increased constriction of the dorsal root fibres is the primary pathological change in tabes dorsalis (Obersteiner and Redlich).

According to Stilling, the number of all the posterior root fibres in a woman, twenty-six years old, was 504,473. Birge's counts concern the frog only. Lewin and Bühler have made counts, the former stating that in the rabbit the number of fibres peripheral from the ganglion is larger than that of the fibres entering the cord by 19 per cent. in the rabbit, and the latter maintaining an excess of 25.5 per cent. in the frog. Hardesty has shown for the frog that the number of fibres in the dorsal root decreases as the fibres pass from their cells of origin in the spinal ganglion. Dale made counts of the fibres on both sides of the spinal ganglion and found an average excess of only 0.5 per cent. on the distal side. The theories explaining the distal excess have been discussed by Hardesty, who made many counts, and whose article is referred to above.

A most important study of the medullated nerve fibres in the dorsal roots of the spinal nerves of man is that of Ingbert. In brief he has found:

1. The total area of the cross-sections of the dorsal roots of the left spinal nerves of a large man is 54.93 mm.
2. The total number of medullated nerve fibres in the dorsal roots of the left spinal nerves of the same man is 653,385; and the total number on both sides would therefore be about 1,306,770.
3. There are, on the average, 11,900 medullated nerve fibres to every square millimetre of the cross-sections of the dorsal roots of man.
4. There is a close relation between the area of the cross-sections of the dorsal roots and the number of nerve fibres which they contain (see Chart III.).
5. The small fascicles of a dorsal spinal root in general contain nerve fibres of small calibre.

Spinal Cord.

6. The number of nerve fibres per square millimetre of the cross-section may vary considerably in the different fascicles of the same dorsal spinal root.

7. According to the estimate made, about sixty per cent. of the medullated nerve fibres in the dorsal roots of the spinal nerves of both sides, or 784,062 fibres, go to innervate the dermal surface, and about forty per cent., or 522,708, are sensory fibres distributed to muscles and deep tissues. The afferent fibres of spinal-ganglion origin, passing in the rami communicantes, are not separately considered in this estimate, but for the moment are classed with those passing to the deeper tissues.

8. According to Ingbert's estimate, one cutaneous nerve fibre in the dorsal spinal roots innervates on the average 1.7 mm.^{2} of the dermal surface of the arm, 1.4 mm.^{2} of that of the head and neck, 2.7 mm.^{2} of that of the entire body, 3.2 mm.^{2} of that of the leg, and 4.1 mm.^{2} of that of the trunk; and for each additional class of nerve fibres assumed, we must increase the area proportionately.

9. If we assume with Foster four classes of cutaneous nerve fibres, then each fibre will have to innervate on the average 5.6 mm.^{2} of the dermal surface of the head and neck and 16.4 mm.^{2} of the dermal surface of the trunk.

Very interesting, too, are the discussions of Dunn on the number and on the relation between diameter and distribution of the nerve fibres innervating the leg of the frog. A description of these findings would exceed the limits of the space here provided, but references to the original articles are given below.

According to Lewin, there are in the rabbit many more spinal ganglion cells than there are fibres in the dorsal root. Thus for 3,200 dorsal root fibres, he found as many as 10,400 spinal ganglion cells. The neurilemma as well as Henle's sheath is arrested at the moment each posterior root fibre passes through the pia. The intramedullary continuations of the posterior root fibres are devoid of neurilemma, though they possess myelin sheaths.

Groups of ganglion cells in the dorsal roots at some distance from the spinal ganglion have been over and again demonstrated. Hyrtl spoke of them as *ganglia aberrantia*. Some of these may be true spinal ganglion cells; others may be sympathetic ganglion cells dislocated from the posterior horn of the gray matter of the cord.

Anterior Funiculus.—The total number of fibres in the anterior funiculus in the frog has been counted by Gaule. In human beings a rather rough estimate has been made by Ziehen, whose numbers are as follows: Intumescentia cervicalis, 46,000; midthoracic region, 28,000; intumescentia lumbalis, 42,000. The same investigator has studied carefully the calibre of the nerve fibres in the anterior funiculus. He finds that fine and coarse fibres are mixed in the upper cervical region, the coarser fibres being toward the periphery and close to the fissura mediana anterior; the finer fibres being relatively more numerous near the gray matter (Figs. 4386 and 4387). The same is true of the cervical enlargement; in fact this mode of distribution holds more or less also through the whole of the pars thoracalis. In the intumescentia lumbalis and in the conus medullaris the distribution of fine and coarse fibres is more even, though on the whole the coarser fibres are somewhat diminished in numbers. It is rare to find fibres measuring more than 20 μ in diameter in the anterior funiculus in any part of the cord. Fibres of 9–12 μ are very numerous. Of the finer fibres some have a diameter no greater than 1.5 μ.

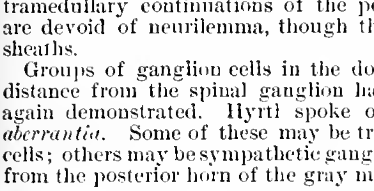

FIG. 4386.—Fibre Grouping in the Funiculus Anterior Near the Anterior Horn. (After T. Ziehen.)

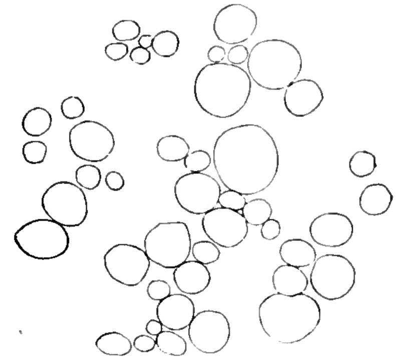

FIG. 4387.—Fibre Grouping in the Periphery of the Funiculus Anterior, Intumescentia Cervicalis. Nigrosin staining. Zeiss Oc. 2, Obj. F. (After T. Ziehen.)

The longitudinal fibres which make up the majority of the fibres of the funiculus anterior run for long distances. A careful study reveals fibres, especially in the medial posterior portion, turning partly posteromedialward to run in the commissura alba anterior, partly lateralward or posterolateralward, to turn into the columna grisea anterior or anterior horn. The fibres which go from the anterior horn to the anterior root are to be seen, running horizontally through the funiculus anterior. Very numerous collaterals are given off in a horizontal or a slightly inclined direction from the fibres of the funiculus anterior.

The distribution of the glia in the anterior funiculus has been described by Gierke, by Weigert, and by Ziehen. True nerve cells are seldom found among the fibres of the funiculus anterior except in the lowermost part of the conus medullaris. Even here they may be confused with large glia cells.

It is in the funiculus anterior that the so-called colossal fibres of lower vertebrates are found. In Teleosts two colossal fibres, often called Mauthner's fibres, are found between the so-called commissura accessoria of fishes (which run from the ventral horn transversely through the funiculus anterior accompanied by gray substance) and the central part of the gray substance. Each of these fibres may have a diameter measuring as much as 110 μ.

Lateral Funiculus.—There are counts of the nerve fibres available for the frog (Gaule) and for human beings (Ziehen). In man exclusive of Lissauer's fasciculus it is estimated that the numbers are about as follows: Intumescentia cervicalis, 275,000; midthoracic region, 240,000; intumescentia lumbalis, 260,000. If the region through which the anterior root fibres pass be added to the lateral funiculus, the numbers just given must be increased by 35,000, 24,000, and 37,000 respectively.

There are great differences in the calibre of the fibres in different parts of the lateral funiculus. Indeed a low-

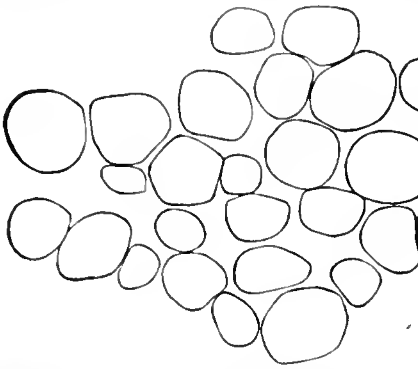

Fig. 4388.—Fibre Grouping in the Periphery of the Funiculus Lateralis. (After T. Ziehen.)

power study of the healthy lateral funiculus will permit one by means of the calibre of the fibres alone to delimit with some degree of accuracy the topographical distribution of the main fasciculi of which the lateral funiculus is made up. At the periphery the coarse fibres predominate, the dorsal portion of the periphery consisting almost exclusively of very coarse fibres (direct cerebellar tract). In the inner portions fine fibres predominate (pyramidal tract and ground bundle) (Figs. 4388 and 4389). The finest fibres in the lateral funiculus, at least in the pars cervicalis, are close to the gray substance (Flechsig's seitliche Grenzschicht der grauen Substanz).

While the majority of the fibres in the lateral funiculus run longitudinally, some fibres running transversely can

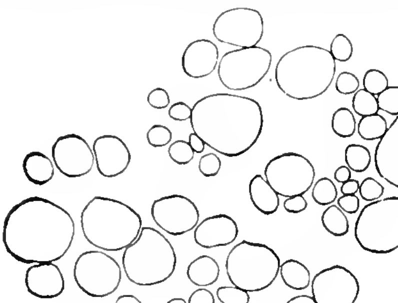

Fig. 4389.—Fibre Grouping in the Interior of the Area of the Lateral Pyramidal Tract; Intumescentia Cervicalis. Nigrosin staining. Zeiss Oc. 2, Obj. F. (After T. Ziehen.)

be seen. Among these may be mentioned the lateral fibres of the anterior root, fibres from the lateral margin of the anterior horn which pass lateralward or dorsolateralward and later assume a longitudinal direction, fibres from the lateral horn which pass dorsolateralward or lateralward, and especially fibres which pass from the neighborhood of the nucleus dorsalis for a short distance transversely and then obliquely upward and lateralward toward the direct cerebellar tract at the dorsolateral periphery. Bundles of fibres belonging to the root of the N. accessorius are to be seen in the upper and middle cervical region. They emerge from the gray matter in the region of the formatio reticularis.

Coming off from the fibres of the lateral funiculus, there can be seen, especially in vertical sections, large numbers of collaterals. They are particularly numerous as the gray substance is approached.

The glia distribution in the lateral funiculus presents no remarkable features.

A relatively large number of ganglion cells stand in close relation to the lateral funiculus. They are situated in the formatio reticularis and in the columna grisea lateralis.

In lower animals "colossal fibres" in various groups have been described in the lateral funiculus.

Posterior Funiculus.—Ziehen's counts of the nerve fibres yield for the posterior funiculus, exclusive of Lissauer's fasciculus, the following figures: Intumescentia cervicalis, 174,000; midthoracic region, 75,000; intumescentia lumbalis, 85,000.

The calibre of the nerve fibres in the posterior funiculus varies greatly and the distribution of the coarse and fine fibres is irregular. It is not easy to set up a sharp distinction between the distribution in Goll's fasciculus (Fig. 4390) and that in Burdach's. At the junction of Goll's and Burdach's fasciculi, the fibres are more closely crowded together than elsewhere. This is the so-called "band of condensation" of Sherrington.

The calibre of the fibres in Lissauer's fasciculus is very small, the average diameter probably not exceeding 2 or 3 μ. This seems to be due to the fact that when the fibres of the posterior root enter the white matter of the cord, the coarse fibres become separated from the fine, the former going into the so-called "entry zone" medial from the posterior horn, the latter accumulating in the interval between the substantia gelatinosa and the periphery of the cord to form Lissauer's fasciculus.

The main stems of the posterior root fibres may run for some distance forward and medialward before undergoing bifurcation into an ascending and a descending limb. In addition to these transverse fibres, one meets at all levels of the cord some longitudinal fibres, which are becoming transverse in order to run in and terminate in the gray matter, and more especially great groups of collaterals given off from different parts of the white matter to run horizontally or somewhat obliquely toward the gray substance. The collaterals of the posterior root fibres are confined chiefly, in the upper part of the cord, to Burdach's fasciculus. It is rare to find them given off from the fibres of Goll's fasciculus. The collaterals of the posterior funiculus are of the highest importance and will be described more fully farther on.

For a description of the glia of the posterior funiculus Weigert's book should be consulted.

It is rare to find dislocated ganglion cells among the fibres of the posterior funiculus, though Sherrington has occasionally met with isolated nerve cells, presumably derived from the nucleus dorsalis (Clarkii).

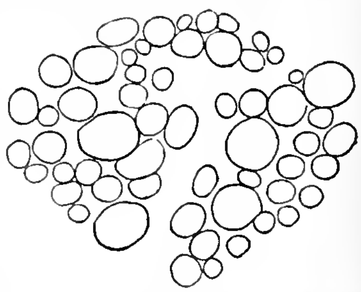

Fig. 4390.—Fibre Grouping in the Fasciculus Gracilis Golli; Intumescentia Cervicalis. Nigrosin staining. Zeiss Oc. 2, Obj. F. (After T. Ziehen.)

The "colossal fibres" so often found in the anterior lateral funiculus of lower vertebrates apparently do not occur in the posterior funiculus.

Each posterior root fibre bifurcates at an angle of from 120° to 160° into a short descending limb and a long ascending limb. The bifurcation takes place at a node of Ranvier. Some collaterals are given off from the root fibre before its bifurcation, but more from the limbs of bifurcation near their origin. It is these limbs of bifurcation which make up the majority of the fibres of the white matter of the posterior funiculus. Since these fibres have their origin in the cell bodies situated in the spinal ganglia, that is, outside the spinal cord, they are often referred to as *exogenous* fibres. As we shall later see, the posterior funiculi contain in addition some *endogenous* fibres, that is, fibres which are processes of cell bodies that are situated within the gray matter of the cord.

Columna Grisea Anterior.—The form and size of the columna grisea anterior or anterior horn varies much, as seen in transverse section, at different levels of the cord. There is a type of form, however, which is characteristic of each segment, and for corresponding parts of segments in different cords, as will be easily seen by a study of the accurate photographic reproductions of sections through each of the segments of the human spinal cord pictured in Alexander Bruce's "Topographical Atlas." An examination of these figures shows that all the motor cells of the anterior horn in the cervical and lumbar regions and in the first thoracic segment may be divided into a *medial* and a *lateral* column of cells. I shall follow Bruce's description closely.

The *medial column* of cells is present throughout the whole length of the cord above the level of N. sacralis V., with the exception of the levels of N. lumbalis I., N. sacralis I., and the upper level of N. sacralis II. This medial column of cells in some sections forms a single group, but in others, especially in the pars thoracalis, is differentiable into an anterior medial column and a posterior medial column. The cells of the latter are smaller than those of the former.

The greatest development of the *anterior medial group* is met with in the levels of the N. cervicalis IV. et V., where besides the cells ordinarily present there is a large group of cells just lateral from them, possibly corresponding to the spinal centre for the N. phrenicus.

Below the level of the N. cervicalis V., the cells of the medial column gradually diminish in number in the cervical segment. In some sections only one or two cells, or even none at all, may be found. The number is again suddenly increased in the lower part of the eighth cervical segment, and this increase, according to Bruce, is maintained throughout the whole of the pars thoracalis.

It is well represented also in the four upper lumbar segments. In the first three lumbar segments Bruce described a few cells in a small anterolateral angle which may be included along with the medial group, or may be regarded as a special anterior group. The medial group of cells is absent in the fifth lumbar, first sacral, and upper part of the second sacral segments, but reappears in the lower part of this segment and is continued as far as the fourth sacral segment. It is absent again below this level.

The *lateral column* of cells is subdivisible in the cervical region into an *anterolateral* (ventrolateral) and a *posterolateral* (dorsolateral) cell column. In the lowermost part of the pars cervicalis an additional group, sometimes designated the *post-posterolateral*, exists. It is also to be found in the first thoracic segment, though the lateral cell column appears to be otherwise entirely unrepresented in the pars thoracalis. In the pars lumbalis, however, in the levels of origin of the Nn. lumbales and upper Nn. sacrales, both an anterolateral and a posterolateral column of cells are present. There is also to be made out, from the level of N. lumbalis II. to the upper part of the segment corresponding to N. sacralis II., a *central* group of nerve cells. Further, a post-posterolateral group of nerve cells (Onufrowicz) exists in the first, second, and third sacral segments. This is the group designated by van Gehuchten as the secondary posterolateral group.

In the pars cervicalis the anterolateral group is really subdivisible into two sections: an *upper anterolateral* section, which extends from the upper limits of the fourth to the upper part of the second segment, attaining its maximum development in the fifth segment; and a *lower anterolateral* group, which extends from the upper third of the sixth to the middle of the eighth segment (Fig. 4391), attaining its maximum development at the seventh segment. The two anterolateral groups thus coexist in the sixth segment (Bruce).

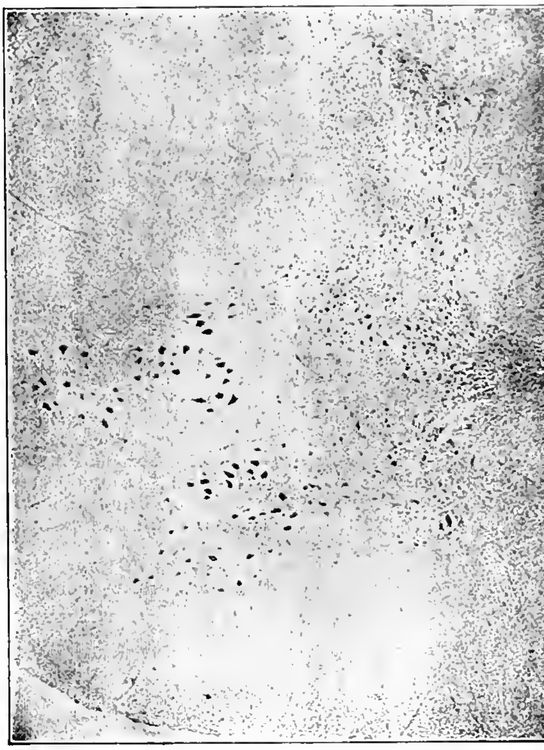

FIG. 4391.—Toluidin Blue Preparation of the Upper Part of the Eighth Cervical Segment of the Human Spinal Cord. (After A. Bruce, "A Topographical Atlas of the Spinal Cord," Edinburgh, 1901.) The anterior mesial group consists of four cells. The posterior mesial is not represented. The antero-lateral and posterolateral groups are more sharply differentiated than in any other segment. The (lower) anterolateral group contains twenty-nine cells. Eleven of these are concentrated into an apparently distinct group at the posterior part of the main group, and consist of larger and more deeply stained cells. The posterolateral group consists of thirty cells, and shows a tendency to division into an inner group consisting of sixteen cells, and an outer group consisting of fourteen cells. Behind there is a post-posterolateral group of three cells.

In the fifth and eighth segments there is an indication of subdivision of the anterolateral group into three subordinate nuclei, one anterior, one medial, and one posterior.

The posterolateral cell column is not present above the fourth cervical segment. Below this level, the cells increase in number rapidly, reaching their maximum at the fifth and sixth segments, where they form the prominent posterolateral angle. This posterolateral cell column is not well marked in the seventh segment, but is increased in size again in the eighth cervical segment, coincident with the marked increase in size of the posterolateral angle in this segment.

The post-posterolateral group begins in the eighth cervical segment and extends through the first dorsal segment. The posterolateral segment gradually disappears from the lower part of the eighth cervical segment, and is absent in the first thoracic segment, although the post-posterolateral group is so well developed in the first thoracic segment that the posterolateral angle still remains prominent in spite of the disappearance of the posterolateral group proper.

In the region of the Nn. lumbales and Nn. sacrales the lateral group of cells first appears at the second lumbar segment, though a small central anterior group of cells is present at the anterolateral angle of the first three lumbar segments.

The anterolateral cell group is enlarged in the fourth and fifth lumbar segments, causing there a special projection of the anterolateral angle; its maximum size, however, is attained at the level of N. sacralis I., below which the group rapidly decreases in size, disappearing entirely before the third sacral segment is reached.

The posterolateral cell group begins rather abruptly in the second lumbar segment, increases rapidly in size below this level, becoming largest in the fourth and fifth lumbar segments. The group undergoes some reduction in size in the first sacral segment, and this diminution goes on gradually through the second and third segments, the cell group disappearing entirely at the lower part of the third sacral segment.

As the researches of Onuf, van Gehuchten, and Bruce have shown, there is some difficulty in deciding upon the lower limits of the anterolateral and posterolateral cell groups in the sacral region, owing to the fact that the posterolateral and post-posterolateral cell groups become displaced forward so that they come to occupy the position previously held by the anterolateral and posterolateral cell groups respectively.

The post-posterolateral cell group has its upper limit in the lumbosacral region in the first sacral segment. It is remarkably developed in the lower half of the second sacral segment, but rapidly diminishes in size again through the third sacral segment, to cease entirely at its lower limit.

The central cell group, peculiar to the lumbosacral region of the spinal cord, extends from the level of N. lumbalis II. to the level of N. sacralis II. It is a tolerably compact column of cells, situated medial from and between the anterolateral and posterolateral groups of cells. It is best developed at the level of N. lumbalis V. and N. sacralis I.

Before leaving the arrangement of cells in the columna grisea anterior, we should say a word or two about a special group of motor cells situated in the upper cervical segments, viz., the *nucleus nervi accessorii*. In sections through the first cervical segment, the posterolateral group of about sixteen cells per section represents the nucleus N. accessorii; in sections through the second cervical segment this nucleus is situated near the middle of the anterior horn, and consists of about eight cells per section; in the third cervical segment the nucleus occupies a position near the middle of the lateral margin of the anterior horn, and there are about five cells per section; in the fourth cervical segment the cells of the nucleus lie slightly behind the anterolateral angle. Some authors class these cells as belonging to the columna intermedio-lateralis rather than to the columna grisea anterior. The relations are well shown in Bruce's "Atlas," Plates I. to IV. The lateral groups of motor cells so richly represented in the enlargements, corresponding to the innervation of the muscles of the extremities, are spoken of collectively in the intumescentia cervicalis as the *nucleus extremitatis superioris*; and in the intumescentia lumbalis as the *nucleus extremitatis inferioris*.

The number of ganglion cells present in the anterior horn of human beings has been estimated for several segments by Kaiser. His figures are as follows:

In the fourth cervical segment, 28,440; in the fifth, 61,230; in the sixth, 44,560; in the seventh, 36,850; in the eighth, 47,970; in the first thoracic segment, 27,600. Kaiser's article contains also the figures for several segments in the spinal cord of the five-months' embryo and of the new-born. Birge's article contains enumerations of the anterior horn cells of the frog.

The form of the anterior horn cell is irregularly polygonal when seen in cross-section, the multangular shape being dependent upon the origin of the dendrites and axones from the cell body.

Anterior horn cells vary in diameter in human beings between 11 and 110 μ (Stilling), though the majority measure from 67 to 135 μ, according to newer measurements. The cells of the posteromedial group average smaller, the diameter varying between 30 and 80 μ (von Kölliker). Ziehen has collected from the literature measurements made in a whole series of animals and he has combined them in a table given on pp. 130–131 of his article (*loc. cit.*).

The growth in size of the anterior horn cells in human beings is well illustrated by Kaiser's measurements in the lateral group of cells of the anterior horn: Fœtus at beginning of fifth month, 16–27.5 μ; at sixth month, 17–33 μ; at seventh month, 23–44.5 μ; at eighth month, 23–48 μ; newly born, 17.5–53 μ; fifteen-year old boy, 26–53 μ; adult 23–59 μ.

Not all the cells of the anterior horns give rise to axones of fibres of the anterior root. Some of them send their axones to the white funiculi of the spinal cord itself, chiefly to the funiculi of the opposite side of the cord through the commissura anterior alba and hence designated "commissural cells" or "heteromeric neurones,"

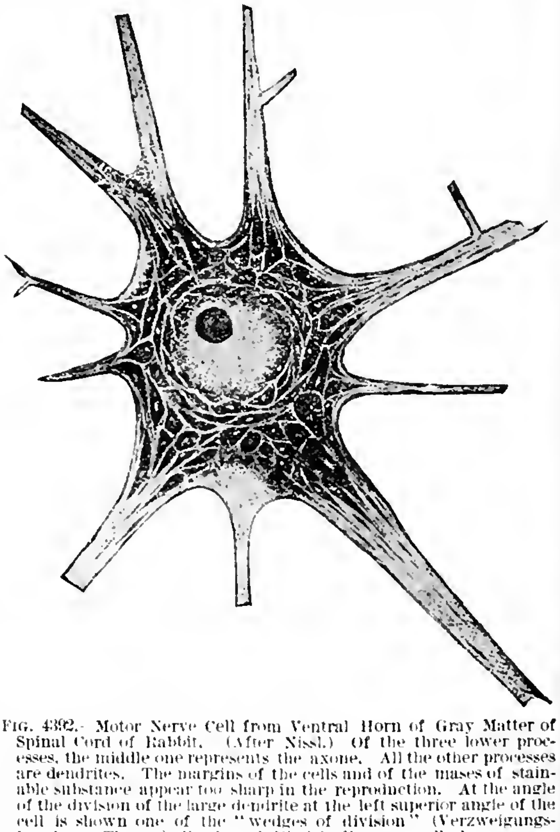

FIG. 4392.—Motor Nerve Cell from Ventral Horn of Gray Matter of Spinal Cord of Rabbit. (After Nissl.) Of the three lower processes, the middle one represents the axone. All the other processes are dendrites. The margins of the cells and of the mases of stainable substance appear too sharp in the reproduction. At the angle of the division of the large dendrite at the left superior angle of the cell is shown one of the "wedges of division" (Verzweigungskegeln). The spindle-shaped Nissl bodies are well shown, especially in the dendrites. This cell is classed by Nissl as a stichochrome nerve cell in the apyknomorphous condition.

but partly to the white funiculi of the same half of the spinal cord, and hence called "tautomeric funicular cells." According to von Lenhossék, the medial group of cells in the anterior horn is made up of commissural cells; he therefore calls it the commissural group, while

Spinal Cord.

the cells whose axones go into anterior root fibres are chiefly limited to the lateral group of nerve cells.

As to the large motor cells of the anterior horn, they form the most prominent elements in cross-sections of the spinal cord. They are typical multipolar stichochrome cells in the sense of Nissl (Fig. 4392). The dendrites pass out in all directions from the cell body, medialward, dorsalward, and some lateralward. They may reach the surface of the cord, having passed through the whole thickness of the white matter; in some animals there is a definite subpial plexus of dendrites. The axone, single for each cell, arises at the axone hillock, and shortly after leaving the cell becomes medullated and passes more or less horizontally through the white matter to enter one of the fila radicularia of the anterior root at the sulcus lateralis anterior. One to four delicate branches, the so-called side fibrils of Golgi, come off from the non-medullated portion of the axone and run back toward the cell body in the gray matter. The differences in calibre of the anterior root fibres have been mentioned above. According to von Bechterew the coarser fibres are medullated earlier than are the finer. It is the opinion of Gaskell and Mott that the coarse fibres are distributed to the voluntary muscles, the fine fibres to the involuntary muscles, by way of the systema nervorum sympathicum. An immense amount of work has been done upon the finer internal structure of the anterior horn cells, a very full résumé of which may be found in my book on the "Nervous System," pp. 101–157. Too much space would be required to introduce the details of structure here.

The glia cells in the anterior horn consist chiefly of typical astrocytes, some with long fibres, some with short. Of the processes of ependymal cells so abundantly present in the gray matter of the embryo cords, relatively little is to be made out in the adult.

In among the nerve cells and glia cells of the anterior horn are to be seen a very large number of medullated nerve fibres and collaterals. These include the medullated proximal portions of anterior root fibres, the medullated axones of tautomeric neurones, the cell bodies of which are situated in the gray matter of the anterior horn, the medullated axones of fibres going to or coming from the commissura anterior alba, the medullated axones and collaterals entering the anterior horn from the anterior and lateral funiculi, and lastly, but among the most important, the reflex collaterals from the posterior root fibres, which pass forward through the gray matter to terminate, as Golgi preparations from the embryo demonstrate, in end-arborizations around the anterior horn cells.

The researches dealing with the relations of the special groups of anterior horn cells to function are numerous. Among others may be mentioned those of Ferrier and Yeo, Risien Russell, Waldeyer, Sano, and Kaiser. M. Allen Starr's table of localization of function in the different segments of the spinal cord is invaluable in clinical diagnosis. (Vide Plate LII. in the present volume.)

Columna Grisea Posterior (Posterior or Dorsal Horn).—The structure of the posterior gray column is much less well understood than that of the anterior gray column. Its gross subdivision into cervix, apex, substantia gelatinosa, and nucleus dorsalis have been described above under the macroscopic appearances. The prominent posterior part, just ventral from the substantia gelatinosa, sometimes called the caput and badly designated, by Waldeyer, *Kern des Dorsalhorns*, is a striking feature in Weigert preparations, since it is closely crowded with medullated fibres and contains relatively small nerve cells.

The nerve cells in the posterior horn are, on the whole, much smaller than those of the anterior horn. The total number of nerve cells present is probably smaller and their distribution and arrangement are irregular. The most constant cell group is the nucleus dorsalis or column of Clarke, which lies at the medial margin of the base of the posterior horn. The nucleus dorsalis is best developed in the lower segments of the thoracic region, and in the segments corresponding to the two uppermost Nn. lumbales. In the intumescentiæ the cells are scanty or absent altogether. In the gray matter of the sacral segments the cells are again more numerous (sacral nucleus of Stilling). There is also a good representation of Clarke's nucleus in the uppermost portion of the cervical cord (cervical nucleus of Stilling). The exact position of the nucleus dorsalis varies in different animals, having a tendency to be situated more dorsalward in human beings than in lower forms. The number of cells in the nucleus dorsalis has not yet been determined. The greatest number in any one cross-section is usually to be met in sections from the segment corresponding to the twelfth thoracic nerve, at which level the nucleus dorsalis measures as much as 0.75 mm. in diameter.

In ordinary carmine or hæmatoxylin preparations the cell bodies of Clarke's nucleus look rounded or elliptical, sometimes polygonal. In Golgi preparations they are shown to be actually multipolar, having very numerous dendrites and a single axone. The dendrites, however, are much less coarse at their roots than are the dendrites of the anterior horn cells, and this accounts for the difference in appearance in carmine preparations. The individual cell bodies vary greatly in diameter, according to Ziehen, between 15 and 70 μ. Von Kölliker's figures are 45–90 μ, while Mott gives as the average diameter 50 μ in the eighth thoracic segment, 109 μ in the twelfth thoracic segment (longitudinal sections).

The single axone from the cell body of a cell of Clarke's nucleus usually arises on the anterior or lateral margin of the cell; occasionally it comes off from the posterior margin. From its origin it runs ventralward, makes a hook-shaped bend, and becoming medullated, either just before or just after making the bend, runs as a transversal nerve fibre to the posterior periphery of the lateral funiculus, where it turns so as to run longitudinally toward the cerebrum in the direct cerebellar tract of Flechsig, the tract which I have designated the fasciculus spinocerebellaris dorsolateralis. These axones, in that horizontal part of their course which is situated between the dorsal horns and the dorsolateral periphery of the cord, make distinct bundles, spoken of as the "horizontal cerebellar bundle" by Flechsig, or as "Flechsig's bundle" by von Lenhossék. Collaterals do not appear to be given off from these axones, at any rate in their proximal portions. As we shall see later, these axones pass through the corpus restiforme of the medulla oblongata to terminate in the cerebellum.

The nerve cells in the caput of the posterior horn, that is, in the so-called *Kern des Dorsalhornes* of Waldeyer, are not well understood. Ziehen designates them *Innenzellen des Hinterhornkopfs.* These cells tend to be triangular in the anterior portion of the group, but become more spindle-shaped in the posterior portion. The smaller cells are partly spindle-shaped, partly polygonal. The size varies greatly. It is rare to find a cell with a diameter of more than 50 μ, while the smallest cells are almost as small as the minute nerve cells of the substantia gelatinosa. The dendrites are long, but not of large calibre. The axone passes in a straight line or in a curve lateralward and becomes a longitudinal fibre, usually ascending, of the lateral funiculus of the same side. Accordingly these cells are to be looked upon chiefly as tautomeric funicular neurones. An occasional axone may pass into the anterior or posterior funiculus, or rarely through the commissure to the opposite side of the cord.

The substantia gelatinosa (Rolandi) contains an enormous number of minute nerve cells, so small that for a long time these cells were believed to be glia cells until Weigert demonstrated that glia cells are really relatively rare in this situation, and Ramón y Cajal, with Golgi's method, demonstrated the exact characters of the nerve cells and their processes situated there. These cells have been very well described by Gierke, and some authors refer to them as *Gierke's cells.* They are usually stellate, though sometimes more spindle-shaped. They are very small; it is rare to find one exceeding 20 μ in diameter. The size varies between 6 and 20 μ. The arrangement in rows is very well shown in Ramón y Cajal's drawings. Each cell has numerous dendrites which have no regular arrangement, though sometimes they form bush-like masses at two extremities of a spindle-shaped cell. The axone arises, nearly always, from the posterior pole of the cell and runs backward, but can seldom be followed beyond the so-called zonal layer, that is, the outermost portion of the substantia gelatinosa which stains less intensely in carmine preparations (*Zonalschicht* of Waldeyer). Ramón y Cajal believes that some of the axones go to form longitudinal fibres of the fasciculus of Lissauer; others to form endogenous fibres of the posterior funiculus; some, doubtless, run longitudinally in the posterior horn itself. Golgi cells of type II., so-called dendraxones, have been described by various authors in the substantia gelatinosa (Rolandi). The finer structure of the cells of the substance of Rolando has been studied by Levi, to whose article we refer for a description of the nucleus and nucleolus.

As early as 1859 Clarke drew attention to the peculiar position occupied by certain cells of the zonal layer of the substantia gelatinosa. These cells, which have been called *marginal cells* by von Lenhossék, and *cellules limitantes* by the French writers, form an uninterrupted row, closest together at the medial margin of the substantia gelatinosa of the posterior horn. Some of them can be followed beyond the substantia gelatinosa, along the medial margin of the posterior horn, even as far as Clarke's nucleus. The individual cells are spindle-shaped, the long axis of the cell running parallel to the margin of the substantia gelatinosa. A few pyramidal cells can be seen, the apex of the pyramid being turned toward the interior of the substantia gelatinosa. These cells are larger by far than the Gierke cells of the substantia gelatinosa itself. The dendrites come off chiefly from the poles of the cells; the axone may arise from the cell body or from a dendrite. It usually passes ventralward through the substantia gelatinosa (Rolandi), where it gives off collaterals (Ramón y Cajal) and then bends lateralward to become a longitudinal fibre of the lateral funiculus. In animals like the chick, mouse, and pig, some axones bifurcate into two, both going to the lateral funiculus, or one going to the lateral, the other to the posterior funiculus. These axones have not yet been followed in human beings.

A very careful study of the glia cells of the posterior horn has been made by Weigert. He it was who demonstrated the relatively small amount of glia in the substantia gelatinosa (Rolandi), a view quite opposed to the older descriptions. There is more glia in the caput of the posterior horn; the nucleus dorsalis is tolerably rich in glia cells. The appearances of the glia of the posterior horn and of the substantia gelatinosa (Rolandi), as revealed by Golgi's method, are well described and pictured by von Lenhossék, to whose article the reader is referred.

The study of the finer and coarser medullated fibres appearing in the posterior horn, made by von Lenhossék, is also one of the best at our disposal. Every one who has studied Weigert preparations of the posterior horn has been struck by the radial bundles of medullated fibres which pass through the substantia gelatinosa (Rolandi), and by the great number of fine fibres present in different parts of the posterior horn.

A large number of the fibres entering the posterior horn of the gray matter are to be looked upon as the terminals of the fibres of the posterior funiculi. As manifold observations have shown, the fibres coming into the posterior funiculus through any given posterior root, vary greatly in their length. Some run into the gray matter to terminate almost at the level of entrance; others run longitudinally in the posterior funiculus, to terminate in the gray matter a few or several segments distant from the level of entrance, while still others run for long distances lengthwise in the posterior funiculus, passing by a great many segments before terminating in the gray matter of the cord, some of them even passing the whole length of the spinal cord above the level of the entrance to find a termination first in the gray matter of the medulla oblongata. Accordingly the posterior root fibres seen terminating in the gray matter at any given level of the cord may have come in through a posterior root near this level, or through a number of posterior roots at variable distances below. A few posterior root fibres instead of running lengthwise in the posterior funiculus assume a longitudinal course within the gray matter of the posterior horn itself.

Much interest has been manifested with regard to the medullated fibres which run in from the fasciculus cuneatus to terminate in the nucleus dorsalis. Von Lenhossék and von Kölliker describe these fibres going to the nucleus dorsalis as collaterals of the posterior root fibres, though Schaffer, of Budapest, maintains that these fibres are the main fibres and not collaterals, and his observations, together with those of Redlich, indicate that it is the fibres from the sacral and lumbar nerve roots which chiefly end in the nucleus dorsalis. The number of fine medullated fibres to be seen in among the cell bodies of the nucleus dorsalis is a striking feature of Weigert preparations.

Whatever may be the facts in the dispute about the nature of the fine medullated fibres in the nucleus dorsalis, there can be no doubt that in addition to the terminals of the stem fibres of the posterior root running into the gray substance, there are immense numbers of collaterals from the posterior root fibres and their limbs of bifurcation passing into the dorsal horn, some of them to end there, others to pass through it and to terminate in the anterior horn. These collaterals are most numerous on the fibres of the fasciculus cuneatus; but they rarely come from the fibres of the fasciculus gracilis; in other

Spinal Cord.

words, the collaterals are given off from the proximal portions of the posterior root fibres rather than from their distal portions.

A group of these collaterals about which we know most is that of the reflex collaterals which come off in a flat curve, slightly convex lateralward, from the root entrance zone and enter the gray matter at the medial margin of the head of the posterior horn, some of them passing through the most medial portion of the substantia gelatinosa (Rolandi). These fibres lie lateral from Clarke's nucleus and from the posterior root fibres which run into the nucleus dorsalis to terminate there. Once inside the posterior horn these reflex collaterals run either straight ventralward or ventralward and slightly lateralward, sometimes forming a second slight curve, the concavity of which is directed medialward. In the anterior horn the collaterals undergo fan-like dispersion and end in terminal arborizations upon the cell bodies and dendrites of the anterior horn cells.

A large number of the radial bundles passing through the substantia gelatinosa are terminals and collaterals from the fibres of Lissauer's fasciculus to the caput of the posterior horn. A certain number of terminals and collaterals from the fibres of the lateral funiculus have been shown by Golgi's method to run into the gray matter of the posterior horn and to end there.

Doubtless some of the medullated fibres seen in the posterior horn are the medullated axones of posterior horn cells on their way to the funiculus lateralis, the funiculus posterior, or the commissure. The horizontal cerebellar path of Flechsig met with at tolerably regular intervals and representing the medullated axones of the cells of the nucleus dorsalis belong to this category.

Columna Grisea Lateralis seu Intermediolateralis.—This column, especially developed throughout the thoracic portions of the spinal cord, includes the nerve cells of the so-called "lateral horn" and of the adjacent reticular formation. J. Lockhart Clarke described it as the tractus intermediolateralis, and pointed out that it was most marked in the upper portion of the pars thoracalis. Many authors have made the mistake of confusing the cells of this lateral column of gray matter with those of the posterolateral group of the anterior horn, and in the cervical and lumbar regions there is still some ground for doubt as to which cells shall be counted as belonging to the columna lateralis and which to the columna anterior.

The bodies of the nerve cells tend to lie in compact groups; the individual cells are usually multipolar, sometimes spindle-shaped. The measurements in the long axis of the cell body are given as varying between 12 and 45 μ, those of the short axis between 5 and 15 μ.

The dendrites which often run far out into the white substance tend to be arranged in oppositipolar groups corresponding to the spindle shape of many of these cells. The single axone goes as a rule to become a longitudinal (ascending or descending) fibre of the lateral funiculus of the same side. The cell bodies of the columna lateralis must therefore be regarded as being those of tautomeric neurones. A few axones probably go to the anterior funiculus of the same side. It has been suggested that some of these cells become anterior root fibres, which go to innervate the abdominal and perineal muscles; but the results of studies by the method of Golgi are opposed to such a view.

Columna Intermedia.—I use this term to designate an important area of gray substance situated between the anterior and posterior horns, and variously named by different authors (*Mittelzone der grauen Substanz*, von Lenhossék; *Zwischentheil* or *Zwischenzone der grauen Substanz*, Ziehen). Here are situated groups of nerve cells which may be called intermediate cells (*Mittelzellen* of Waldeyer, *Zwischenzellen* of Ziehen). They lie anterolateralward from the nucleus dorsalis Clarkii. The arrangement of these cells is more regular and continuous in the upper part of the spinal cord, while in the lower part it is far less regular, the cells being scattered. Argutinsky has described and pictured peculiar aggregations of these cells, which have, however, as he maintains, no segmental significance. The cell bodies are, as a rule, polygonal in shape and vary in size between about 10 and 24 μ in the long diameter. The axones of these cells go chiefly to become fibres of the lateral funiculus, though some have been followed into the anterior funiculus and others into the commissura anterior alba. The corresponding neurones are therefore to be regarded as tautomeric and heteromeric respectively.

Substantia Grisea Centralis.—This includes the gelatinous gray matter surrounding the central canal. The ependymal cells which line the central canal play a large part in the formation of this portion of the gray matter. Some one hundred ependymal cells are required to build up the circumference of the central canal at any one level (Stilling). These cells vary from 10 to 25 μ in breadth, and from 25 to 55 μ in length; these figures refer to the swollen main portion of the cell body and do not, of course, include the long processes (ependymal fibres). The cells are ciliated at their distal end; these cilia are much easier to make out in the embryo than in the adult. The so-called ependymal fibres are really the distal processes of the ependymal cells. The appearance of these fibres in embryonic tissues, stained by the method of Golgi, is very remarkable. The careful descriptions of von Lenhossék and Ramón y Cajal may be consulted in this connection.

In addition to the ependymal cells a larger number of glia cells exists in this region than in the more peripheral parts of the gray matter. The large number of nuclei visible in this region in iron-hæmatoxylin preparations is probably accounted for by the presence of large numbers of glia cells, and the gelatinous appearance around the central canal is due to the large number of ependymal glia cells in the neighborhood. Weigert's glia stain demonstrates an extraordinary richness in glia in this region, the whole area coming out dark blue in the section.

The mode of obliteration of the central canal has been described in detail by Weigert and by Brissaud, to whose descriptions the reader is referred.

True nerve cells would appear to be absent in the immediate neighborhood of the central canal. In the more peripheral portions of the substantia grisea centralis a few cell bodies can be found, part of them those of neurones whose axones go to the lateral funiculus, others those of commissural neurones.

In the gray commissure there are many white fibres which appear to be independent of the commissura anterior alba. These tend to be combined into two delicate white commissures which run in the gray commissure, one in front of the central canal (commissura intracentralis anterior), and one behind the central canal (commissura intracentralis posterior).

The *commissura intracentralis anterior*, identical with Stilling's commissura anterior accessoria, is sharply separable from the commissura anterior alba, lying as it does behind the latter in the gray matter. Its constituent fibres are very much finer than those of the anterior white commissure. The bundle is most marked in the intumescentia lumbalis and in the conus terminalis. According to Ziehen, the majority of the fibres, namely, those more anteriorly situated, are connected (by origin or termination) with the anteromedial group of nerve cells in the anterior horn. The more posterior fibres of this little commissure he follows to the junction of the columna intermedia with the substantia grisea centralis, and concludes that they here assume a longitudinal direction.

The *commissura intracentralis posterior* consists of very fine fibres, and is best developed in the proximal portion of the pars cervicalis and in the conus medullaris, being only feebly represented in the thoracic cord and in the intumescentiæ. Exact measurements of the sagittal diameter are given by Stilling.

Much work has been done upon the origin and termination of the fibres of this posterior intracentral commissure. The view now held is that many of them represent reflex collaterals from the posterior root fibres of one side of the cord, which go through this commissure to terminate in the opposite anterior horn. In addition, some collaterals from fibres of the lateral and posterior funiculi pass through this commissure to end in the posterior horn. Again, some of the cells in the posterior horn give off axones which, becoming medullated, pass through this commissure to the opposite posterior horn, to end there, or to become endogenous fibres of the opposite posterior funiculus. Ziehen also describes in the commissure fibres which arise from the cells of the columna intermedia and from the cells of the columna intermediolateralis, but the termination of these fibres he could not ascertain.

The Conduction Paths of the Spinal Cord.

We have thus far considered the white matter and the gray matter more or less separately without any special reference to the interrelations of the nerve cells to the nerve fibres. Investigations have shown that functionally similar nerve fibres tend to run in definite bundles of the white matter, and that functionally similar groups of nerve cells tend to lie in common masses or columns in the gray matter. The bundles of fibres of common function are known as *fibre systems*. The functional groups of nerve cells are known as *nerve centres* or *nuclei*. Histological examination proves that these nerve centres or nuclei are connected with specific fibre systems. Each nerve cell of a particular nucleus gives off an axone, which becomes the medullated nerve fibre of a definite fibre system. Since the nerve-cell body or perikaryon with its dendrites and axone, with the collaterals and termination of the latter, is, as a whole, known as a *neurone*, it is obvious that we may speak of a nerve centre, or nucleus, together with its corresponding fibre system, as a *neurone system* (systema neuronicum). It is to the various neurone systems and the modes of localizing them in the spinal cord that it is our intention next to turn. We shall see that the term *conduction path* is used in a wider sense to include a chain of superimposed or subimposed neurone systems, the end arborizations of the axones of one neurone system transferring the nerve impulses to the dendrites and cell bodies of the neurone of the next neurone system in the chain. A good spatial sense is necessary for the proper understanding of the conduction paths; unless one is capable of thinking of the three dimensional relations inside the central nervous system, he will have great difficulty in understanding the problems connected with them.

While, as we have said, there is a marked tendency to aggregation of fibres of similar function in localized areas of the white matter of the cord, it must not be thought that this localization is as sharp as many of the diagrams in the text-books would lead one to believe. Indeed, there is undoubtedly much mixing of fibre systems in given areas of a cross-section, and when we designate a certain area as that of the lateral pyramidal tract, for example, it must be understood that this nomenclature is employed for *a fortiori* reasons, for we know that in the area a few fibres other than those belonging to the pyramidal tract exist.

The methods which are employed for the localization of the conduction paths are as follows:

1. *Weigert's Myelin-Sheath Method.*—This method, described in the article *Brain, Histology of*, permits one in serial sections to follow medullated axones for very considerable distances. Unfortunately, it is not of great service in demonstrating the connection of the nerve cells with the nerve fibres, for even when carmine or other dyes are used as a contrast stain for the cell body and axones, it is often very difficult to follow an axone into its corresponding medullary sheath.

2. *Method of Golgi.*—This method, chiefly applicable to embryonic tissues, has proved to be of exrtraordinary value in demonstrating developing dendrites, axones, collaterals, and telodendrions. It permits us to follow the axones of the various anterior horn cells to the anterior roots or to the anterior white commissure, or to the funiculi. It, more than any other method, has permitted the determination of the funicular relations of the axones of the posterior horn cells, and has given us most precise information regarding the intramedullary course of the axones of the fibres of the posterior roots. Finally, by means of this method, we have gained an entirely new conception of the relations of the terminals of the axones of one neurone system to the cell bodies and dendrites of the next neurone system in given conduction paths. The method has, unfortunately, a limited application in the study of the adult spinal cord.

3. *Method of Flechsig* (Observations of Serial Medullation).—Though a number of investigators before Flechsig had observed that different portions of the white substance developed their myeline sheaths at different periods, it was Flechsig who first took advantage of this fact in a large way for determining the serial sequence of medullation. He also utilized the facts discovered for drawing inferences with regard to the topographical localization of conduction paths. Flechsig's studies proved that in human embryos of the same age the same groups of nerve fibres are medullated in the white substance, while embryos at different ages reveal an entirely different grouping of the medullated fibres. In other words, the medullation of the different fasciculi is temporarily constant and follows a definite law. After studying a series of embryos, one can, if he knows the age of the embryo, say off-hand what bundles of fibres in the cord will on examination be found to be medullated, and what bundles will still lack myelin sheaths. Flechsig further found that nerve fibres having the same origin and termination, that is, nerve fibres of the same fibre system, and which therefore probably have the same function, become medullated at the same period, while other fibres, with different anatomical connections and different functions, become medullated at other times.

Figs. 4393, 4394, and 4395.—Figures Illustrating the Dorsal Funiculi in the Cervical, Thoracic, and Lumbar Regions of the Spinal Cord. Those on the left side illustrate the embryological memberment, those on the right side the lesions in cases of incipient tabes. (After P. Flechsig, *Neurolog. Centralbl.*, Leipzig, Bd. ix., 1890, S. 73.) Lettering explained in text.

Flechsig, by this method, was able to distinguish easily in the funiculus anterior two parts: (1) the pyramidal tract of the funiculus anterior; and (2) the ground bundle or fasciculus lateralis proprius of this funiculus. In the lateral funiculus a study of the medullation separates sharply (*a*) the pyramidal tract of the lateral funiculus (*fasciculus cerebrospinalis lateralis*); (*b*) the direct cerebellar tract (*fasciculus cerebrospinalis*,) or, better, *fasciculus spinocerebellaris dorsolateralis*); and (*c*) the ground bundle of the lateral funiculus (*fasciculus lateralis proprius*). This embryological method goes even further and divides the fasciculus lateralis proprius into an internal part, the lateral limiting layer of the gray matter (*seitliche Grenzschicht der grauen Substanz*), and an external part, the anterior mixed zone of the lateral funiculus (*vordere gemischte Seitenstrangzone*). In the posterior funiculus the fasciculus gracilis (Golli) becomes medullated, on the whole, at a different period from that for the fasciculus cuneatus (Burdachi). The embryological method, however, permits of a much finer analysis still of the posterior funiculus, as we shall have occasion to point out later on.

In general it may be said that a study of embryos in four stages, at lengths of 25 cm., 28 cm., 32 cm., and

50 cm. respectively, gives a tolerably clear idea of the medullation sequence in the spinal cord. Thus, in human embryos 25 cm. long, there are myelin sheaths upon the fibres of (1) the commissura anterior alba; (2) the fibres of the anterior roots and some of the fibres of the posterior roots; (3) the fibres of the fasciculus anterior proprius; (4) the fibres of the anterior mixed zone of the lateral funiculus; and (5) many of the fibres of the fasciculus cuneatus (Burdachi). In embryos 28 cm. long the fibres of the fasciculus gracilis (Golli) have also largely acquired their myelin sheaths. In embryos 32 cm. in length the lateral limiting layer of the gray matter in the fasciculus lateralis proprius is medullated, and in embryos a little older the direct cerebellar tract and Gowers' tract are found to be medullated. Finally, the anterior and lateral pyramidal tracts become medullated only at birth, when the fœtus has attained a length of about 50 cm.

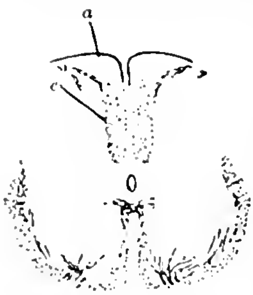

FIG. 4396. Lumbar Portion of Spinal Cord of Human Fœtus 24 cm. Long. *a*, Dorsal part of funiculus posterior; *c*, ventral part. (After Trepinski.)

It will have been noticed that the sequence of medullation corresponds to the probable development serially of the more sharply defined nervous functions. Thus, as we should expect, the peripheral nerves become medullated first, and the apparatus for central excitation in the cord (not in the brain) is furnished. The provision for the simpler reflexes is followed by myelinization of the fasciculus lateralis proprius and the fasciculus lateralis anterior, thus permitting of the connection of adjacent and somewhat distant segments with one another corresponding to the neural apparatus underlying the more complex reflexes. The longer centripetal tracts connecting the cord with the medulla and cerebellum become medullated later, corresponding to still more complex reflexes and to the coördination of movements and the maintenance of equilibrium. It is at a very late period when the fibres connecting the cord with the cerebral cortex are medullated, and even later when the fibres of the pyramidal tracts, throwing the anterior horn cells under the influence of the cerebral cortex, receive their myelin sheaths.

FIG. 4397. — Thoracic Portion of Spinal Cord of Human Fœtus 24 cm. Long. (After Trepinski.)

It is necessary to give a few details bearing upon the sequence of medullation. The fibres of the posterior roots do not begin to be medullated until after the process has well begun in the anterior roots. Indeed the myelinization of the posterior root remains, on the whole, dilatory as compared with that of the anterior root. Von Bechterew has divided the posterior roots into two fibre systems, the first corresponding to medullation at the fourth month of fœtal life, the second to a medullation process most marked near the end of intra-uterine life. Later studies by Flechsig and Trepinski make it seem certain that at least five fibre systems are to be distinguished in the posterior roots. As they correspond to five similar systems in the posterior funiculus, they need no further description.

FIG. 4398. Lumbar Portion of Spinal Cord of Human Fœtus 28 cm. Long. (After Trepinski.)

Flechsig divided each funiculus posterior, exclusive of the fasciculus gracilis (Golli), into the following areas: (1) the anterior root zone (*vordere Wurzelzone*); (2) the middle root zone (*mittlere Wurzelzone*); (3) the posterior or dorsal root zone (*hintere Wurzelzone*); (4) the median zone (*mediane Zone der Hinterstränge*). Flechsig gives the name *ovales Centrum* to the oval area in the lumbar region made up of the median zones of the two sides. The middle root zone contains two fibre systems which develop at different periods and are called the *first and second systems of the middle root zone*. Similarly the posterior or dorsal root zone contains two fibre systems, the *medial and lateral systems of the dorsal root zone* (Figs. 4393, 4394, and 4395). The fibre systems receive their myelin sheaths in the following sequence: (1) the anterior or ventral root zone (*V.r.z.*); (2) the first system of the middle root zone (*M.r.z.*) and the median zone; (3) the fasciculus gracilis (Golli), the second system of the middle root zone and the medial portion of the posterior or dorsal root zone (*D.r.s.*); (4) lastly, the lateral portion of the dorsal root zone, namely, Lissauer's fasciculus.

FIG. 4399.—Thoracic Portion of Spinal Cord of Human Fœtus 28 cm. Long. (After Trepinski.)

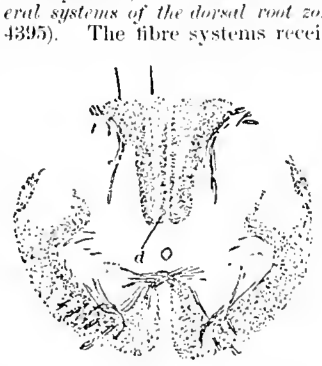

FIG. 4400.—Cervical Portion of Spinal Cord of Human Fœtus 28 cm. Long. (After Trepinski.)

A still more careful analysis has been made by Trepinski, who makes out, exclusive of Lissauer's fasciculus, four distinct fibre systems in the posterior funiculus. These fibre systems are medullated in fœtuses 21 cm., 28 cm., 35 cm., and 42 cm. long respectively. The areas of the different systems overlap somewhat.

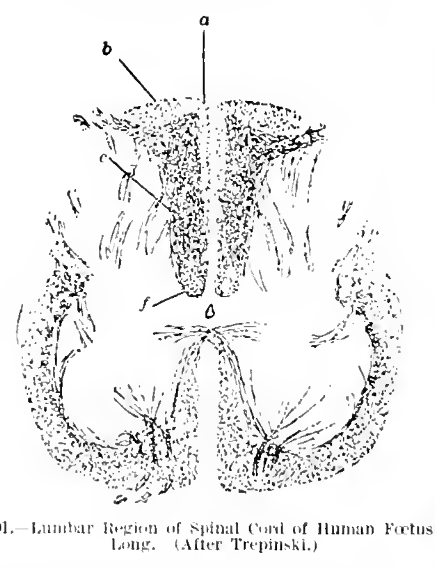

FIG. 4401.—Lumbar Region of Spinal Cord of Human Fœtus 35 cm. Long. (After Trepinski.)

In fœtuses 24 cm. long (Figs. 4396 and 4397) the poste-

Spinal Cord.

rior part of the funiculus in the lumbar region shows no medullated fibres, though the more ventral parts show evenly scattered medullated fibres. In the pars thoracalis and pars cervicalis the medullated fibres form a narrow stripe along the septum medianum posterius (Flechsig's median zone) and a somewhat broader stripe along the posterior horn (Flechsig's anterior root zone). These medullated stripes go over into one another in the most anterior region of the funiculus.

In fœtuses 28 cm. long (Figs. 4398, 4399, and 4400) the posterior funiculus in the lumbar region is medullated throughout, the second fibre system obviously being distributed over the whole cross-section. In the thoracic cord medullated fibres have appeared throughout the cross-section, but a light area is visible in the middle region of the funiculus, forming a stripe which goes from the posterior periphery almost to the anterior extremity of the funiculus. In the cervical cord of the fœtus 28 cm. long, the fasciculus gracilis looks pale, except for a narrow stripe near the median septum (Flechsig's median zone). This darker area is continuous anteriorly with the medullated area corresponding to the fasciculus cuneatus which is now well medullated.

In fœtuses 35 cm. long (Figs. 4401, 4402, and 4403) the third fibre system is medullated. A large number of new fibres have appeared in the lumbar cord in an area corresponding to Flechsig's middle root zone. In the cross-section this area is limited posteriorly by a curved line, behind which the posterior funiculus is pale in Weigert sections. There is another light stripe near the median septum, and a third light area in the most anterior part of the funiculus. The thoracic cord of the 35 cm. fœtus presents an entirely different appearance from that of the fœtus of 28 cm. The anterolateral part of the fasciculus cuneatus has received many new fibres; the posterolateral part of this fasciculus looks light in Weigert preparations. In the cervical cord at this stage the third fibre system is seen to be distributed throughout the greater part of the fasciculus cuneatus; a small area in the most posterior region of the funiculus shows no increase in fibres. The fibres in the medial portion of the fasciculus gracilis are increased. The lateral part of this fasciculus now looks light.

In fœtuses 42 cm. long the whole posterior funiculus (with the exception of Lissauer's fasciculus) is evenly medullated; the fibres which fill up the light areas of the fœtus 35 cm. long may therefore be regarded as belonging to Trepinski's fourth fœtal system. Lissauer's fasciculus is not wholly medullated even in fœtuses 47 cm. long.

To recapitulate, Trepinski's studies indicate that there are at least five fibre systems in the posterior funiculus.

1. A fibre system, including a part of the anterior portion of the funiculus in the lumbar cord, and a stripe along the posterior horn, along the gray commissure and along the posterior median septum in the thoracic and cervical cord.

FIG. 4402.—Thoracic Portion of Spinal Cord of Human Fœtus 35 cm. Long. (After Trepinski.)

2. A fibre system distributed over the whole area of the posterior funiculus, the fibres being more numerous in the posterior than in the anterior part of the lumbar cord, most scanty near the septum intermedium in the thoracic cord and in the fasciculus gracilis in the cervical cord, though the median zone of Flechsig is well medullated.

3. A fibre system distributed over the whole funiculus in the lumbar cord, except in Flechsig's median zone and the medial part of his posterior zone; spread all over the thoracic and cervical posterior funiculus with the exception of Flechsig's median zone, the medial part of his posterior zone, and the lateral part of the fasciculus gracilis.

4. A fibre system distributed in the posterior portion of the lumbar cord (medial posterior root zone of Flechsig), the anterior part of the funiculus and a stripe along

FIG. 4403.—Cervical Portion of Spinal Cord of Human Fœtus 35 cm. Long. (After Trepinski.)

the posterior part of the median septum; in the thoracic and cervical cord this fibre system is also distributed in the lateral part of the fasciculus gracilis.

5. A fibre system corresponding to Lissauer's fasciculus.

4. *Method of Waller or Türck* (Study of Secondary Degenerations).—This method takes advantage of the fact that if a medullated axone be interrupted anywhere in its course by cutting, pressure of a tumor or the like, secondary or Wallerian degeneration takes place in the cellulifugal portion of the fibre, the portion of the fibre between the point of injury and the cell body which gives origin to the axone remaining uninjured for a considerable period of time. The finer changes characterizing this secondary or Wallerian degeneration have already been described in a previous article in this HANDBOOK (see *Neurone, General Pathology of*, in Vol. VI.).

As a rule, the secondary degeneration does not extend beyond the telodendrion of the axone concerned, that is to say, it is confined to the neurone which is injured. There are certain exceptions to this rule, exceptions which have been used in an absurdly unfair way as arguments against the existence of neurones, but in general the rule given holds. This method of the study of secondary degeneration has been one of the most fruitful of all the methods employed for the unravelling of conduction paths. It is applicable to degeneration in human beings, following disease or injury, and also to degenerations experimentally produced in animals by section or other modes of experimental injury. For a long time the application of this method was confined to cases in which the degeneration had gone far enough and was extensive enough to be studied by Weigert's myelin-sheath method, but more recently much greater advances have been made through the application of the extremely delicate method of Marchi, which permits of the detection of small groups of fibres, and even of single degenerated fibres a very short time (twelve to fifteen days) after the injury.

The method of secondary degenerations permits us, for example, to make out, at any given level of the cord, the number of fibres which are passing centripetally at that point, that is, ascending, and the number of fibres which are passing centrifugally at that level, that is, descending. Since every nerve fibre is dependent somewhere upon the nutritive influence of a nucleus in the cell body or perikaryon, that is to say, is a prolongation of a cell, when the nerve fibre is separated from its cell of origin, the peripheral part, being cut off from its trophic centre, necessarily undergoes degeneration.

If we cut through the spinal cord of an animal at any given level, all the nerve fibres cut through will inevitably degenerate on the cellulifugal side from the lesion. Thus above the plane of section there will be degeneration of all the ascending nerve fibres, that is to say, of all the fibres whose axones come from the nerve cells situated below the level of the section. On the other hand, below the plane of section there will be degeneration of all the descending fibres, that is to say, of all the fibres whose axones come from nerve cells situated above the plane of the lesion. The majority of the ascending fibres will be sensory; the majority of the descending fibres will be motor. Some of the ascending and some of the descending fibres will belong to neurones whose function it is to connect neighboring segments of the cord for participation in complex reflexes; it would be difficult to designate these axones as specifically sensory or specifically motor.

An excellent list of the most important observations on degeneration after transverse lesions of the human spinal cord is given by Ziehen on pages 246 and 247 of his monograph. There are observations for nearly every segment down as far as the second lumbar. The list is too long to be included here, but it will be found convenient for reference.

If transverse lesion of the human spinal cord has taken place in the pars thoracalis, there will, in general, be found degeneration, above the plane of the lesion, of the following centripetal bundles:

1. The whole of the posterior funiculus, including Lissauer's fasciculus, with the exception of a few centrifugal fibres to be described among the descending degenerations.

2. The peripheral zone of the lateral funiculus, including the direct cerebellar tract (fasciculus cerebellospinalis) in the dorsolateral periphery and Gowers's tract (fasciculus anterolateralis superficialis) in the ventrolateral periphery.

3. A part of the fibres of the lateral limiting layer of the gray matter (*zone cornumarginale* of French authors).

4. A part of the fibres of the anterior mixed zone of the lateral funiculus (funiculus lateralis proprius).

5. A large part of the fibres of the anterior ground bundle (fasciculus anterior proprius).

6. A large part of the fibres of the peripheral zone of the anterior funiculus, not only on the surface, but also along the fissura mediana anterior.

7. A few fibres scattered throughout the region occupied by the fasciculus cerebrospinalis lateralis or lateral pyramidal tract.

Below the level of the lesion there will be found degenerated the following:

1. The lateral pyramidal tract in the lateral funiculus (fasciculus cerebrospinalis lateralis).

2. A part of the fibres of the peripheral zone of the more ventral portion of the lateral funiculus.

3. A few of the fibres of the lateral limiting layer of the gray matter.

4. A part of the fibres of the anterior mixed zone of the lateral funiculus (fasciculus lateralis proprius).

5. A few of the fibres of the anterior ground bundle (fasciculus anterior proprius).

6. A few of the fibres of the peripheral zone of the anterior funiculus (Loewenthal's tract) from the cerebellum to the cord.

7. The pyramidal tract of the anterior funiculus (fasciculus cerebrospinalis anterior).

8. A comma-shaped layer of fibres at the junction of the fasciculus gracilis (Golli) with the fasciculus cuneatus (Burdachi) in the posterior funiculus.

9. A narrow layer near the septum medianum posterius (Flechsig's centrum ovale).

10. Lower down, a triangular field in the posteromedial portion of the posterior funiculus (dorsomedial sacral bundle of Obersteiner, *triangle médian* of Gombault et Philippe).

11. A few fibres in the most anterior portion of the posterior funiculus (*zone cornucommissurale* of Marie).

The method of the study of secondary degenerations has also been most useful in determining the exact intramedullary distribution of the fibres of the posterior roots of spinal nerves. Further reference to this fact will be made when the individual conduction paths are taken up.

5. *Method of von Gudden* (Method of Development Inhibition).—Von Gudden's observations led him to believe that in a new-born animal a fibre system extending between two centres would atrophy if either centre were destroyed. But while the fibre system atrophies in either case, if one of the two centres be destroyed, the other will atrophy, not if it be the exciting one, but only if it be the one excited. For example, destruction of the retina, he maintained, would lead to an inhibition of the development of the whole visual path as far as the colliculus superior and the lateral geniculate body, but destruction of the superior colliculus itself would not inhibit the development of the retina, and destruction of the cortical visual area would not hinder the development of the superior colliculus, or the optic nerve or the retina. Observations and experiments since his time indicate that sometimes, at least, the extirpation of the centre excited is followed by an inhibition of the development of the exciting centre; thus the extirpation of the visual area in the cortex may be followed by imperfect development of the optic nerve. It has further been shown that amputations in the new-born cause some inhibition of development of the motor regions of the cortex and of the pyramidal tract, besides causing atrophy of the corresponding anterior horn cells in the spinal cord. On the other hand, extirpation of the motor area of the cortex in the new-born does not lead necessarily to atrophy of the anterior horn cells of the spinal cord, as von Gudden believed, but clinical and pathological observations render it probable that such atrophy is sometimes produced. Ziehen formulates the modified law as follows: If, in a new-born animal, before the central nervous system is fully developed, a conduction path be cut through, a centre destroyed, or a sense organ or a muscle extirpated, the conduction paths and centres therewith connected suffer an inhibition of development in so far as and in the degree that they are deprived of excitations. Thus centres and tracts which, as a result of the injury, receive no impulses, or almost none, fail to develop. This explains why the motor cells of the anterior horn often remain intact after cortical lesions, for even after the cortical injury they receive impulses continuously by way of the reflex collaterals from the posterior root fibres. The occasional occurrence of inhibited

development of sensory nerves after cortical extirpation might be explained on the theory that as a result of the loss of conscious sensations, for example from the eye, conscious movements of the same, on account of their uselessness, would gradually cease to occur, and with the limitation of the movements an important nutritive stimulus would disappear. Whether an inhibition of development would then occur, and in what degree, would depend upon the number of accidental circumstances (number of stimuli of reflex movements, etc.) (Ziehen).

In the application of the method Weigert's myelinesheath procedure and carmine staining are to be employed. A reduction in size of one-third on one side of the nervous system, as compared with the normal opposite side, traceable through a series of sections, is the criterion to be observed.

By this method most important information has been gained with regard to the visual conduction paths, the auditory conduction paths, the lemniscus, and the pyramidal tract.

6. *Method of Gotch and Horsley* (Electrophysiological Method).—This method is a physiological one and depends upon the variation of the electrical current on excitation of a conduction path; it determines the path followed by the impulses and hence the course followed by the axones of the fibre systems themselves.

REFERENCES.

Gotch, F., and Horsley, V.: On the Mammalian Nervous System, its Functions and their Localization Determined by an Electrical Method. Phil. Tr., 1891, London, 1892, vol. clxxxii. (B.), pp. 267–526.

By means of these various methods the centripetal and centrifugal conduction paths of the spinal cord have been and are being worked out. The centripetal paths include the paths carrying sensory impulses to cerebellar and cerebral centres, the sensory limbs of reflex arcs in the cord and the centripetal intersegmental paths. The centrifugal paths include the pyramidal tracts, the cerebello-spinal paths, and other centrifugal paths connecting the infracortical nuclei of the cerebrum with spinal centres, as well as the centrifugal intersegmental paths of the cord itself. To a description of some of the principal paths here mentioned we shall now turn.

A. *The General Sensory or Centripetal Paths in the Spinal Cord.*

It seems natural to begin with a description of the neurone systems concerned in the construction of the general sensory conduction paths from the skin, muscles, and organs to the nerve centres of the cord and to the higher centres in the brain. The conduction paths here concerned are very complex, but this is not to be wondered at when one recalls the complexity of reflex, instinctive, and voluntary reactions in which they participate, and when he remembers that these paths are the recipients of all the impulses from the skin, mucous membranes, and muscles below the head—impulses which probably vary in origin and character according as they are interpreted in consciousness, as touch, muscle sense, heat, cold, or pain. We might, from physiological observations, expect to find anatomically in the spinal cord separate conduction paths for touch, for heat, for cold, for muscle sense, and for pain. It is easy to demonstrate anatomically a large number of different centripetal fibre systems in the cord, but as to just how these differ in function and as to just what paths subserve the various modalities of sensation we are very poorly informed. It is true that there is some evidence for the view that tactile sensory impulses run in the lateral funiculi, and preferably though not exclusively, after crossing from the side of the cord in which they enter to the opposite side; and, further, that the muscle sense impulses (kinæsthetic excitations) run in the posterior funiculi, chiefly on the side of entrance. Anatomy teaches that all the centripetal impulses, no matter the sensation modality to which they correspond, enter the spinal cord through the fibres of the posterior roots. Most of the fibres of the posterior roots terminate at some level or another in the spinal cord or medulla oblongata. These fibres we know to be the axones of neurones, the cell bodies of which are situated in the spinal ganglia. By means of the terminals and collaterals of these axones the impulses arriving along them in the spinal cord may be transferred to several sets of central neurones; these latter carry the impulses farther and are designated as neurones of the second order in the general centripetal path. On the way from the periphery to the cortex of the brain the centripetal impulses have to pass through a chain of at least three superimposed neurone systems, and in many instances a very much larger number of neurone systems may take part in the concatenation.

It will be convenient to describe, first, the centripetal neurone systems of the first order, and to go on afterward with the description of the sensory neurone systems of the second and of higher orders, as far as these are present in the spinal cord.

1. *Peripheral Sensory Neurone Systems* (Centripetal Neurone Systems of the First Order).—These neurone systems include all the neurones which send processes to the periphery of the body below the head, to receive impulses from the skin, mucous membranes, muscles, tendons, and joints, and which send their central axones through the posterior roots of the spinal nerves into the posterior funiculi of the spinal cord. The cell bodies of these neuroné systems are all situated in the spinal ganglia. The proximal portions of the central axones as well as the whole extent of the peripheral axones of these neurones are situated outside the spinal cord. Only those portions of the central axones which extend from the pia onward are intramedullary; the intramedullary axones, being derived from cell bodies extramedullary in situation, are designated "exogenous fibres of the spinal cord."

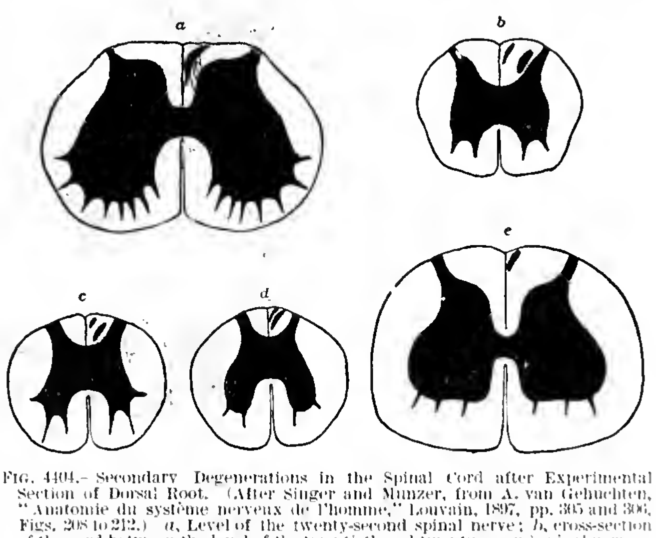

FIG. 4404.—Secondary Degenerations in the Spinal Cord after Experimental Section of Dorsal Root. (After Singer and Munzer, from A. van Gehuchten, "Anatomie du système nerveux de l'homme," Louvain, 1897, pp. 305 and 306, Figs. 208 to 212.) *a*, Level of the twenty-second spinal nerve; *b*, cross-section of the cord between the level of the twentieth and twenty-second spinal nerves; *c*, transverse section through the cord at the level of the eighteenth spinal nerve; *d*, transverse section of the cord in the thoracic region; *e*, transverse section of the cord at the level of the intumescentia cervicalis.

The study of secondary degenerations occurring in disease in human beings, or produced experimentally in animals, has thrown much light upon the distribution of the intramedullary continuations of the posterior root fibres, particularly since the method of Marchi has been applicable. Section of a posterior root in an animal causes complete degeneration of the intramedullary continuation of the fibres of that root to their termination. Serial sections show a progressive diminution in the number of fibres which are the continuations of the fibres of a given root as the cord is ascended, owing partly to a progressive diminution in the calibre of the fibres, but chiefly to the fact that the fibres of each root as they ascend stop at different levels to end in the gray matter. Moreover, there is a gradual change in the position occupied by the degenerated fibres as the cord is ascended. Thus fibres which low down in the cord are situated in the "entry zone" near the gray matter, come, higher up, to occupy a more medial and more posterior position; they pass gradually medialward through the fasciculus cuneatus until finally they come to lie, at higher levels, in the fasciculus gracilis. Each posterior root as it enters the spinal cord displaces the fibres of the fasciculus cuneatus in a posterior and medial direction, so that the long ascending fibres gradually approach the posterior median septum. Fig. 4404 shows the results of section of the posterior roots of the twenty-sixth, twenty-seventh, and twenty-eighth spinal nerves on one side and the posterior roots of the twentieth, twenty-first, and twenty-second nerves of the same side in a dog.

A number of human cases are on record in which injuries affecting posterior roots at different levels have been observed. The following list is important for reference:

The lesions at various levels following an isolated lesion of N. thoracalis VI. are shown well in Fig. 4405, *A* (Margulies' case).

P. Marie has divided the posterior root fibres into short fibres, long fibres, and fibres of intermediate length (*fibres courtes, fibres longues, et fibres moyennes*).

The exact course followed by the descending limbs of bifurcation of the posterior root fibres has not been ascertained satisfactorily as yet in any human case. Experiments on animals indicate that the descending limbs of bifurcation are short, running in to terminate in the gray matter within one or two segments of the level of entrance of the corresponding posterior root.

By Marchi's method it has been demonstrated that the fibres of the fasciculus gracilis which reach the medulla oblongata, nearly all turn in to end in the nucleus funiculi gracilis, while those of the fasciculus cuneatus which reach the medulla oblongata turn in to end in the nucleus funiculi cuneati. A certain number, however, of those fibres which ascend in the fasciculus gracilis are continued as posterior external arcuate fibres into the restiform body to end in the cerebellum, while others go as internal arcuate fibres to decussate in the raphe. Some of the fibres of the fasciculus cuneatus also go by way of the retiform body to end in the cerebellum without being interrupted in the nucleus funiculi cuneati.

Sections of the spinal cord stained by Weigert's myeline sheath method show many fibres extending from the posterior funiculi into the gray matter of the cord. These have been proven by other methods to be partly terminals, partly collaterals of the posterior root fibres.

Golgi's method has helped us a great deal in the interpretation of these fine medullated fibres of the Weigert's specimens, and indeed has revolutionized our conception of the mode of branching and termination of the posterior root fibres in general. By Golgi's method it is very easy to demonstrate the Y-shaped bifurcation of each posterior root fibre, soon after its entrance into the cord, into an ascending and a descending limb, each of which turns to run in the longitudinal direction, the ascending limb for a long distance, the posterior limb for a short distance, both ultimately terminating in the gray matter (Fig. 4406). This method, too, has revealed the large number of collaterals given off by the stem fibres, by the descending limb of bifurcation, and by the proximal portion of the ascending limb of bifurcation; it has also shown us how the terminals of the limbs of bifurcation themselves as well as the collaterals come into relation with the dendrites and cell bodies of the centripetal neurones of the second order, situated in the various groups of nerve cells of that gray matter.

It is very hard to state definitely in all cases how many of the fine fibres going from the posterior funiculi into the gray matter of the cord, as seen in Weigert preparations, are collaterals and how many are terminals of posterior root fibres. Of the groups to be immediately considered the reflex bundles appear to be made up chiefly of medullated collaterals, while the fine fibres going to end in the nucleus dorsalis are probably chiefly terminals of ascending limbs of bifurcation of posterior root fibres.

The fine medullated fibres going into the gray matter are divisible into at least four principal groups: (1) those ending in the columna grisea posterior and in the columna grisea intermedia; (2) those passing from the fasciculus cuneatus partly through the substantia gelatinosa, partly medial from it, forming S-shaped curves and ending in the anterior horns; these bundles, largest in the intumescentiæ, make up the reflex collaterals, each of which terminates by multiple division in among the cell bodies and dendrites of the lower motor neurones of the anterior horn; (3) those coming from the middle area of the fasciculus cuneatus and ending in the nucleus dorsalis (Clarkii); the bundles, reaching the posterior surface of the gray column, split into two divisions, one of which passes to each side of the nucleus, so that in cross-sections the nucleus dorsalis reminds one of a berry on a stem; (4) those running into the posterior intracentral commissure and ending chiefly in the opposite posterior horn.

The studies of Flechsig and Trepinski on the successive medullation of the intramedullary continuations of the posterior root fibres have already been referred to. We know that the fibres of a given root are not medullated all at once, but we are not sure in how far the differentiation of the posterior funiculus, yielded by Flechsig's method of study, is due to the successive medullation of groups of fibres as wholes, and how much of it is due to the successive medullation of different parts of the same fibres. It might very well be that the proximal portion of the posterior root fibres are medullated earlier than the distal portions; or, again, it is easily conceivable that the stem fibres and the two limbs of bifurcation may become medullated before the collaterals, or that some collaterals from one fibre become medullated before other collaterals from the same fibre. Until we are better informed upon these points we shall be at a loss in the making of classifications for the subdivisions of the peripheral neurone systems now under consideration.

At present two subdivisions are justifiable, but in how far one corresponds to the other we do not know. The

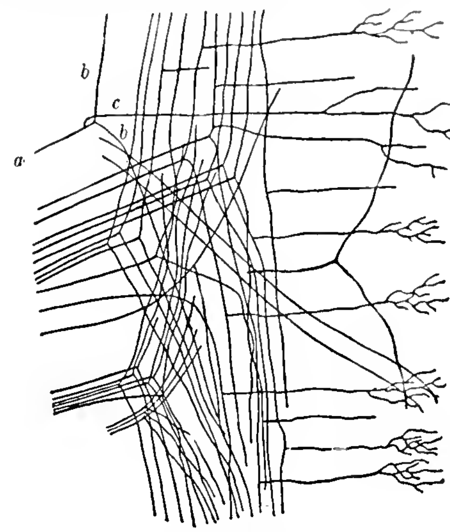

FIG. 4406.—Entrance of the Fibres of the Dorsal Roots into the Dorsal Funiculus of the Spinal Cord of an Embryo Calf. (After A. van Gehuchten, "Anatomie du système nerveux de l'homme," Louv., 2 ed, 1897, p. 302, Fig. 205.) A stem fibre, *a*, is seen dividing into two branches, *b*, *b*, the ascending and descending limbs of bifurcation. From the stem fibre, *a*, a collateral, *c*, is seen to arise. A number of collaterals arising from the limbs of bifurcation of other fibres are illustrated.

first subdivision, based upon successive medullation, has already been discussed. The second subdivision, that usually given in the text-books, is based upon the distribution of the terminals and collaterals of the posterior root fibres in different gray centres (*nuclei terminales*). Thus there may be distinguished (1) a direct ascending posterior funicular path (*direkte aufsteigende Hinterstrangbahn* of the Germans), including the long fibres of the fasciculus gracilis and fasciculus cuneatus which terminate in the rhombencephalon, chiefly in the nucleus funiculi gracilis and nucleus funiculi cuneati; (2) the path ending in the nucleus dorsalis (Clarkii); (3) the path ending in the posterior horn; (4) the reflex path ending in the anterior horn.

The *direct ascending path of the posterior funiculus* probably corresponds to several of Flechsig's fibre systems, not to any one of them. It is quite possible, therefore, that this path will, in the future, be further subdivided, inasmuch as its fibres are being medullated throughout the whole latter half of intra-uterine life. Clinical observations in tabes dorsalis and in transverse myelitis indicate that the muscle sense of the corresponding half of the body runs in the direct ascending path of each posterior funiculus—a view quite in accord with the observations in Brown-Séquard's paralysis, and with Mott's experimental hemisections in monkeys.

The *fibres running in to end in the nucleus dorsalis (Clarkii)* are, as Schaffer has shown, in all probability the terminals of ascending limbs of bifurcation of posterior root fibres rather than collaterals, although both may be concerned. Weigert preparations and Golgi preparations indicate that these fibres, as they ascend in the posterior funiculus, tend to run in Flechsig's middle root zone. My studies on hereditary ataxia lead me to think that at any rate a large part of these fibres correspond to the third fœtal system of Trepinski. Since the funiculus dorsalis is largely confined to the thoracic levels of the cord, it seems very likely that the fibres of the posterior funiculi which terminate in this nucleus are derived principally from the posterior roots of the Nn. lumbales and Nn. sacrales. They seem to correspond to the "fibres of intermediate length" of P. Marie's classification. His "long fibres" belong to the direct ascending path of the posterior funiculus, and his "short fibres" to the path to the posterior horn. Against the view that the path to Clark's nucleus corresponds to the third fœtal system of Trepinski, it might be urged that Flechsig states that medullation of these fibres begins in fœtuses 19–20 cm. long. Redlich has, however, expressed the opinion that the majority of fibres going to Clark's nucleus become medullated at a much later period—a view which my studies tend to corroborate. It is of course quite thinkable that the path to Clark's nucleus may later have to be subdivided into a number of different fibre systems, corresponding to different periods of medullation and perhaps to differences in functional significance. The individual fibres running in to end in the nucleus dorsalis are of small calibre, and each fibre breaks up into an end arborization which comes into relation with several cells of the nucleus. As to their function, the findings in cases of hereditary ataxia above referred to indicate that these fibres carry the impulses which, when transmitted through the direct cerebellar tract to the cerebellum, prevent that coarse variety of ataxia so pronounced in the individuals affected in the family described by Dr. Sanger-Brown. They can be concerned, however, only with impulses derived from the lower extremities and the trunk.

The *path to the posterior horn* includes the fibres which ascend in the posterior horn itself, the fibres which run in the posterior funiculus and turn in to end in the posterior horn, and the terminals and collaterals of the fibres of Lissauer's fasciculus. The majority of them appear to be fibres which end a short distance above the level of the posterior root, to which they belong. As they become medullated at very different periods, they probably consist of a series of embryological fibre systems. The majority of the fibres are small; they end in telodendrions about the cells of the substantia gelatinosa, the cells of the zonal layer, and the cells of Waldeyer's nucleus of the posterior horn. It is believed that the impulses concerned in tactile, painful, and thermic sensations enter the cord through these fibres, but the evidence has been gained *per exclusionem* rather than in any other way.

The *reflex path to the anterior horn* consists chiefly of collaterals which come off from the posterior root fibres and run forward in S-shaped curves, partly through the medial portion of the substantia gelatinosa, partly through the interval between the substantia gelatinosa and the nucleus dorsalis in regions of the cord in which the latter is present. They end in telodendrions about the anterior horn cells. It seems probable that each ascending limb of bifurcation of a posterior root fibre may give off several such reflex collaterals; others doubtless come off from the descending limb of bifurcation, and some from the stem fibres themselves before the bifurcation. The majority of the reflex collaterals go to the anterior horn of the same side of the cord, but some of them pass through the posterior intracentral commissure to reach the anterior horn of the opposite side. These reflex collaterals begin to be medullated in fœtuses 28 cm. long, but the medullation continues through several months. The fibres are of fine calibre; on their integrity depend the superficial and deep reflexes. It seems very probable that the main fibres which go to form the direct ascending path of the posterior funiculus give off the reflex collaterals—that is to say, the same neurones which serve to conduct impulses to the cerebral centres which are concerned in consciousness are utilized also to carry the impulses which set free reflexes.

A word must be said about the *descending limbs of bifurcation of the posterior root fibres.* In the case of secondary degeneration, studied by Dejerine and Thomas, in the cervical region the descending fibres of a posterior root extended over three segments in the form of an anteroposterior stripe situated in the lateral part of the fasciculus cuneatus. In Schaffer's case of lesion of the fifth lumbar root the degeneration was slight, being represented by an anteroposterior stripe extending from the posterior commissure to the posterior surface of the funiculus, and running parallel to the posterior median septum. The comma-shaped degeneration met with in the posterior funiculus after transverse lesion of the cord appears to be due to degeneration of endogenous fibres (which I have designated as the fasciculus posterior proprius) rather than to descending fibres of the posterior root.

2. *Central Sensory Neurone Systems* (Centripetal Neurone Systems of the Second Order).—We have seen that the central axones of the peripheral neurone systems (centripetal neurone systems of the first order) end in various masses of the gray matter of the spinal cord and medulla—the so-called terminal nuclei of the peripheral sensory spinal nerves. Among these terminal nuclei we have mentioned the nucleus funiculi gracilis and nucleus funiculi cuneati of the medulla oblongata, the nucleus dorsalis (Clarkii) on each side, and the gray matter of the posterior horn or columna grisea posterior. In these terminal nuclei are situated the cell bodies and dendrites of neurones of the second order, the axones of which carry the impulses farther.

The medullated fibres which correspond to the axones coming from the nuclei of the posterior funiculi in the medulla oblongata go to form, after decussation, the medial lemniscus (cf. article *Brain, Histology of*). It will not be further discussed here.

The medullated axones coming from the cell bodies situated in the nucleus dorsalis (Clarkii) form a very important fibre system, the so-called "direct cerebellar tract," or Flechsig's bundle. It is sometimes described as the fasciculus cerebellospinalis, but I prefer to designate it the *fasciculus spinocerebellaris dorsolateralis.* This fibre bundle, recognized by Foville, Türck, and Meynert, was first exactly described by Flechsig. The axones come off from the cells in Clarke's nucleus, turn horizontally lateralward in curves to reach the posterolateral periphery of the funiculus lateralis, and then turn in the longitudinal direction to run the whole length of the cord and pass through the corpus restiforme to end in the cerebellum. The fibres receive their myeline sheaths at about the sixth or seventh month of fœtal life. The fibres are of very large calibre, measuring from 3 to 10 μ in diameter, the majority measuring from 6 to 8 μ. They stand close together and are often sharply recognizable in normal Weigert preparations as a distinct compact mass, which contrasts with the neighboring pyramidal bundles.

As the nucleus dorsalis is represented below the thoracic cord only by the sacral nucleus of Stilling, only a few fibres corresponding to the direct cerebellar tract are to be found below the twelfth thoracic segment (Fig. 4407).

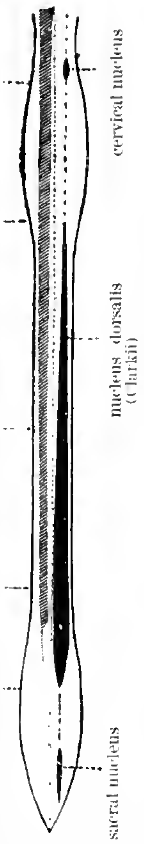

FIG. 4407.—The Column of Clarke and the Direct Cerebellar Tract. The situation and volume of the column of Clarke are shown as a heavy black band on the right; those of the direct cerebellar tract are represented by a striated black band on the left. (From Poirier et Charpy, "Traité d'anatomie humaine," t. iii., 2 ed., Paris, 1901, p. 206, Fig. 146.)

The bundle of fibres occupies a comma-shaped field in the lower thoracic cord corresponding to the third and fourth fifths of the periphery of the lateral funiculus, counting from the front. In the upper thoracic cord it may displace the lateral pyramidal tract from the periphery and extend backward as far as Lissauer's fasciculus. In the cervical region it occupies the whole dorsal half of the periphery of the lateral funiculus except at the level of N. cervicalis II., where the posterior seventh of the periphery is occupied by the lateral pyramidal tract. The medial portion of the area of the tract throughout its whole extent is overlapped slightly by the area of the lateral pyramidal tract, the fine fibres of the latter being mixed with the coarser fibres of the former. On the whole, however, the limitation as seen under a low power is tolerably sharp.

The area of the tract increases steadily in the cross-sections, as the cord is ascended. There has been some dispute as to whether all of the fibres of the tract go to the cerebellum, or whether some end at different levels in the gray matter of the cord; the weight of opinion, at present, is in favor of the former view. The fibres ultimately terminate in the vermis superior (Flechsig, von Monakow, Mott). As has already been pointed out, the tract always undergoes ascending secondary degeneration in transverse lesions of the thoracic cord. I have called attention in another place to the marked liability of this tract to injury in acute cerebrospinal meningitis, owing doubtless to its exposed position on the surface of the cord ("On Certain Changes in the Cells of the Ventral Horns and of the Nucleus Dorsalis [Clarkii] in Epidemic Cerebrospinal Meningitis," *Brit. Med. Jour.*, London, 1897, ii., pp. 1839–41). Studies in tabes and in hereditary ataxia make it seem probable that the neurone system of the second order, to which the fibres of this tract belong, conducts to the cerebellum the group of centripetal impulses concerned in the automatic regulation by the cerebellum of the body equilibrium.

The medullated fibres which correspond to the axones coming from the cells of the gray matter of the posterior horn, give rise to several fibre systems, among which may be mentioned the superficial anterolateral fasciculus of Gowers, the fasciculus anterior proprius, the fasciculus lateralis proprius, and the fasciculus posterior proprius.

The *fasciculus anterolateralis superficialis (Gowersi)* is also, in the main, an ascending tract from the spinal cord to the cerebellum. I have suggested that this main part of it be called, therefore, the *fasciculus spinocerebellaris ventrolateralis*. Developmentally, it is a part of Flechsig's anterior mixed zone of the lateral funiculus. The exact position of the cells in the gray matter, which give off these axones, is not yet known. It seems probable that they are in the posterior horn, or in the columna intermedia between the posterior horn and the anterior horn, and it is certain that while some of the cells of origin are in the gray matter of the same side, many of them are in the gray matter of the opposite side of the cord, the crossing taking place through the commissura anterior alba. Hence the neurones, to which the fibres of Gowers' tract belong, are partly tautomeric, partly heteromeric neurones. The fibres become medullated at the beginning of the eighth fœtal month (von Bechterew). The calibre of the fibres varies a good deal; some of them are coarse, others fine.

The tract begins in the lumbar portion of the spinal cord, where it lies in the middle of the periphery of the lateral funiculus, occupying about one-seventh of that periphery. Higher up, as the area of the tract increases in size, the additions are made chiefly anteriorly. In the cervical and upper thoracic cord the area occupied by the tract extends from the anterior extremity of the area of Flechsig's direct cerebellar tract to near the sulcus lateralis anterior. The shape of the area as seen in cross-section varies a good deal in different human cases. The area is not sharply limited, either medialward or dorsalward, as it is overlapped slightly by the area of the direct cerebellar tract of Flechsig and by other fibre systems of the fasciculus lateralis. Mixed up with the fibres of Gowers' tract, which are ascending, are some fibres of descending tracts, as secondary degenerations show.

There is a good deal of evidence in support of the view that not all of the fibres of Gowers' tract reach supraspinal terminations, many of them ending in the gray matter of the cord on the way up. It is possible that some of them pass dorsalward to run farther upward in the direct cerebellar tract of Flechsig. The course of Gowers' tract through the medulla oblongata and pons has been followed by Patrick and by Hoche. It goes cerebralward as far as the colliculus inferior and then runs backward through the velum medullare anterius, along with the fibres of the brachium conjunctivum to end in the vermis superior, partly on the same side, partly on the opposite side (Fig. 4408).

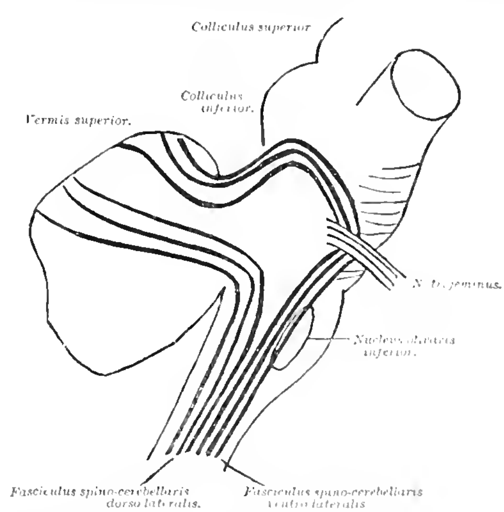

FIG. 4408.—Diagrammatic Representation of the Course of the Fibres of the Two Principal Tracts Ascending from the Spinal Cord to the Cerebellum. (After F. W. Mott, *Brain*, Lond., vol. xv., 1892, p. 219, Fig. 1.) The fasciculus spinocerebellaris ventrolateralis Gowersi and the fasciculus spinocerebellaris dorsolateralis are united in the cord and in the lower part of the medulla. The latter passes into the corpus restiforme and terminates in the dorsal portion of the superior vermis. The former remains ventrally situated until it reaches the level of the N. trigeminus; passing beyond this it forms a loop backward to reach the dorso-lateral surface of the brachium conjunctivum. The fibres then course backward and sweep round into the anterior portion of the superior vermis.

In addition to the main portion of Gowers' tract, which represents a spinocerebellar neurone system by way of the brachium conjunctivum (systema neuronicum spinocerebellare ventrolaterale conjunctivale), there are in the tract fibres which end in the superior colliculus of the corpora quadrigemina (systema neuronicum spinoquadrigeminum superius), fibres which end in the thalamus (systema neuronicum spinothalamicum), and fibres which go to the cerebellum by way of the corpus restiforme (systema neuronicum spinocerebellare ventrolaterale restiformale). If Rossolimo's observations should be confirmed, there are also, in Gowers' tract, fibres which terminate in the inferior colliculi, in the substantia nigra, and in the nucleus lentiformis.

As to the function of Gowers' tract there is much dispute. Gowers himself thought that the tract might conduct pain impulses. It seems more probable, however, that the function of this tract is similar to that of the direct cerebellar tract of Flechsig.

The *fasciculus anterior proprius*, *fasciculus lateralis proprius*, and *fasciculus posterior proprius* may next be discussed. Secondary degenerations show that these fasciculi are made up partly of ascending fibres, partly of descending fibres; partly of fibres coming from cells of the gray matter of the same side of the cord, partly of fibres coming from cells of the gray matter of the opposite side of the cord. Of these three fasciculi, the fasciculus lateralis proprius is by far the most voluminous. The fasciculi proprii become medullated early in fœtal life and are of great interest to the clinician, since in them are to be sought, as far as we can now see, the paths which conduct the impulses concerned in the sensations of touch, temperature, and pain.

The centripetal neurones of the second order, whose axones run in the fasciculus anterior proprius, may be divided into two sets: (1) those of ascending axones (*ascending centripetal path of the fasciculus anterior proprius*), and (2) those of the descending axones (*descending centripetal path of the fasciculus anterior proprius*). The ascending path is made up of medullated axones coming chiefly from the cells in the interior of the posterior horn, partly from the same side, partly from the opposite side, through the anterior white commissure. In the anterior funiculus these fibres are situated at the periphery in front and along the anterior median fissure (*zone sulcomarginale* of Marie). The fibres are mixed up with the descending path of Loewenthal, and with the path which corresponds to the medullated axones of the commissural cells of the anterior horn. These fibres probably terminate at various levels of the gray matter of the cord, sending their impulses on through centripetal neurone systems of the third order, though this view is hypothetical. We have but few facts as yet to record concerning it. The descending path has been shown by Golgi's method to be made up of axones which come from cells in the interior of the posterior horn of the same or of the opposite side. These descending fibres are practically all descending limbs of bifurcating axones, so that the path pertains to the same set of neurones which gives rise to the ascending path. The fibres end in all probability after a shorter or longer (though never very long) course in the gray matter of the anterior horn. Whether they enter into conduction relation chiefly with the motor cells or with the commissural cells of the anterior horn is not known, but in either case they would participate in the setting free of the more complex spinal reflexes.

The centripetal neurones of the second order, whose axones run in the fasciculus lateralis proprius, may also be divided into two sets: (1) those with ascending axones (*ascending centripetal path of the fasiculus lateralis proprius*); and (2) those with descending axones (*descending centripetal path of the fasciculus lateralis proprius*). The ascending path corresponds to the medullated axones of the marginal cells of the posterior horn and of the nerve cells in the caput of the posterior horn, partly of the same side, partly through the posterior intracentral commissure of the opposite side. The fibres of this path run partly in the anterior mixed zone among the fibres of Gowers' tract and of Marchi's descending cerebello-spinal path, partly in the lateral limiting layer of the gray matter. These fibres are very fine in calibre. Most of them are short, extending over only one, two, or three segments, after which they run in to end in the gray matter of the cord, where they come into conduction relation with centripetal neurones of the next higher order (columna intermedia, columna intermediolateralis). It is this path, made up of a whole series of neurones with relatively short axones superimposed upon one another, that has to do, in all probability, with the conduction of tactile, painful, and thermic sensory impulses. Since tactile sensations developed presumably phylogenetically, it is perhaps not surprising that the neurones forming the path for them should have axones which extend over only one to three metameres. This path is designated by Ziehen the "*aufsteigendes Binnenbahnsystem des Seitenstrangs.*" The descending path of the fasciculus lateralis proprius consists of the medullated descending limbs of bifurcation of those axones from the cells of the posterior horn which go to the lateral funiculus and bifurcate into ascending and descending branches. They run chiefly in the lateral limiting layer of the gray matter, though some of them are mixed up with the fibres of the lateral pyramidal tract. They probably have a reflex function.

The centripetal neurones of the second order, whose axones go to the posterior funiculus, give rise similarly to *an ascending and a descending centripetal path in the fasciculus posterior proprius*. The ascending path corresponds to the medullated axones of all three kinds of cells in the posterior horn—Gierke's cells, the zonal or marginal cells, and the cells of the caput. The axones come partly from the same side of the cord, partly from the opposite side through the posterior intracentral commissure. They run longitudinally in the most ventral portion of the posterior funiculus. This path remains intact in tabes dorsalis. It is the endogenous bundle of the posterior funiculus and does not degenerate after posterior root lesions, though some posterior root fibres may be mixed up with the fibres of this tract. Most of the fibres are short, turning in to end in the gray matter of adjacent levels; among them, however, are some fibres which are much longer. Their function is unknown; it may perhaps be assumed that they have to do with the more complex reflexes. The descending path in the fasciculus posterior proprius has been much better studied. Being endogenous, it often remains intact in tabes; it may be found degenerated in cases of syringomyelia. The tract is made up of fibres from the posterior horn cells, and corresponds chiefly to the descending limbs of fibres which undergo T-shaped bifurcation in the posterior funiculus. These fibres correspond to the comma-shaped area of degeneration of the upper part of the cord, to the "oval field" of Flechsig lower down, and still lower to the "triangle" of Gombault and Philippe. This tract, in all probability, corresponds to the "descending septomarginal tract" of Bruce and Muir, and to the *dorsomediales Sacralbündel* of Obersteiner. It must not be forgotten that circumscribed as this bundle is, there are always some fibres derived from the posterior roots mixed with its endogenous fibres. The function of the descending tract in the posterior funiculus is unknown, though Mann has suggested that it has something to do with the innervation of the Mm. intercostales.

B. Centrifugal Neurone Systems in the Spinal Cord. (Central Motor Neurones.)

Under this heading are to be considered the neurone systems, the axones of which enter into conduction relations with the cell bodies and dendrites of the lower motor neurones of the anterior horns. The central motor neurones, by means of this conduction relation, which their axones establish with the lower motor neurones, help to form the general motor conduction path from the higher centres of the brain to the muscles of the body. The lower motor neurones have cell bodies and dendrites in the gray matter of the spinal cord, but only the proximal portions of their axones are in the cord itself; the main portions of the axones lie peripheral to the cord, forming the anterior roots and the motor portions of the peripheral nerves; the axones finally terminate in motor end-plates (telodendrions) on the muscle fibres. These lower motor neurones are thrown under the direct influence of the peripheral sensory neurones by means of the reflex collaterals from the posterior root fibres. They are less directly under the influence of the peripheral sensory neurones by means of intercalated associative central neurones in the cord, the axones of which help to make up the ascending and descending fibre systems of the fasciculi proprii. They are still more remotely under the influence of the peripheral centripetal neurones by means of the conduction relations which are established between the central sensory neurones (the axones of which terminate in higher centres) and the upper motor neurones of the general motor conduction path. It is these upper motor neurones which must now be considered.

Cerebrospinal Motor Neurones (Neurones the Axones of which Make up the Fibres of the Pyramidal Tracts).—These are the neurones the cell bodies and dendrites of which are situated in the motor area of the cerebral cortex, and the axones of which run downward to terminate about the motor cells of the anterior horns. These neurones mediate the conscious movement impulses sent out from the brain voluntarily to the spinal cord (and thus toward the muscles). The axones leaving the cortex run through the centrum semiovale of the hemisphere, help to form the corona radiata of the capsula interna and pass through the anterior two thirds of the posterior limb of the capsule. In the capsula interna the fibres governing the movements of the upper extremity are in front of the fibres controlling the movements of the lower extremity. Below the internal capsule the

fibres run through the base of the cerebral peduncle at about its middle, plunge through the basilar part of the pons, helping to form the longitudinal fasciculi of that region, to reach the medulla oblongata, where they form the well-known fasciculi pyramidales, which on each side correspond to the pyramis medullæ oblongatæ, which can be seen from the surface. In the lower part of the medulla oblongata the fibres undergo a partial decussation, the so-called decussatio pyramidum, which takes place

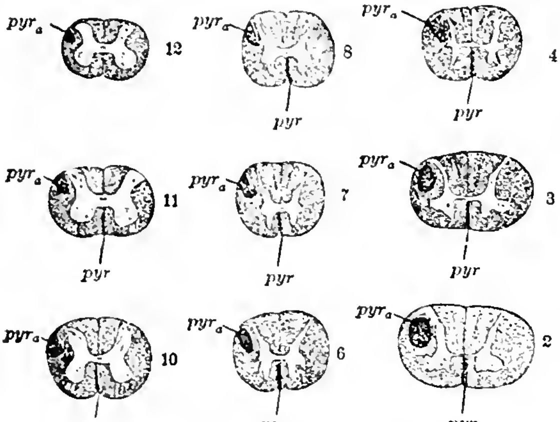

FIG. 4410.—Degenerated Fibres in the Spinal Cord of the Same Case as that shown in (Fig. 4409). 1–3, pars cervicalis; 4–8, pars thoracalis; 9–12, pars lumbosacralis; *pyr*, fasciculus cerebrospinalis ventralis; *pyra*, fasciculus cerebrospinalis lateralis.

throughout a distance of about 1 cm. The fibres, in their crossing, pass through the gray matter of the anterior horn into the opposite lateral funiculus. A portion of the fibres of each pyramid remains uncrossed, going down chiefly as an uncrossed bundle in the funiculus anterior of the same side of the spinal cord. A few fibres, however, pass downward in the funiculus lateralis of the same side. The fasciculus cerebrospinalis anterior or anterior pyramidal tract is therefore an uncrossed fibre system, while the fasciculus cerebrospinalis lateralis is a fibre system chiefly crossed, but containing a few uncrossed fibres (Figs. 4409 and 4410).

The lateral pyramidal tract, or fasciculus cerebrospinalis lateralis in the cervical portion of the spinal cord, occupies a large area in the posteromedial region of the lateral funiculus. Its volume decreases rapidly as the cord is descended and the relative position of the fibres undergoes some alteration. Owing to the fact that the direct cerebellar tract is not present below the thoracic cord, the lateral pyramidal tract in the lumbosacral region comes to lie adjacent to the periphery of the cord.

The decrease in volume as the cord is descended is owing partly to a progressive diminution in the calibre of the fibres, but chiefly to the fact that constituent fibres of the bundle leave it at each segment to turn into the gray matter of the anterior horn, to end there. More fibres turn in to end in the segments which correspond to the cervical and lumbar enlargements than elsewhere in the cord, since it is over the muscles innervated by these segments that the cerebrum exercises the most refined control (muscles of the upper and lower extremities).

The fibres of the anterior pyramidal tract (fasciculus cerebrospinalis anterior) decrease also in number as the cord is descended, the loss in it being very great in the region of the intumescentia cervicalis. The fasciculus is entirely exhausted on its way through the thoracic cord, none of its fibres reaching as far as the lumbar cord. The majority of the axones of the anterior pyramidal tract run in to terminate in the anterior horn of the same side, but a few of them pass through the commissura anterior alba to end in the anterior horn of the opposite side.

The fibre systems of the pyramidal tracts are exquisitely localizable by the embryological method of Flechsig, since at birth practically all the fibres of the spinal cord, with the exception of the pyramidal tracts and the little tract in the upper cervical region known as Helweg's path, are fully medullated. This is an interesting fact, for the medullated axones of the lower motor neurones are among the first of all the nerve fibres of the body to be medullated. Accordingly the corticomuscular conduction path in its lower part (anterior roots and motor nerves) is medullated and presumably ready for function long before its upper part (pyramidal tracts), the explanation being that the lower part of the corticomuscular conduction path also subserves the function of the motor limb of the direct reflex conduction paths.

The embryological method throws much light upon the variations in decussation which occur in the lower part of the medulla oblongata. The lateral pyramidal tracts are never entirely absent. They usually make up from eighty to ninety per cent. of the total volume of the cerebrospinal fasciculi, but the proportion varies a great deal, more fibres crossing in one case than in another. In rare cases as few as ten per cent. of the fibres go over into the lateral funiculus, the remaining ninety per cent. continuing downward in the anterior funiculus. In other rare instances the whole pyramidal tract goes over into the lateral funiculus and the fasciculus cerebrospinalis anterior is absent. There is sometimes asymmetry on the two sides, the asymmetry more often affecting the anterior pyramidal tract than the lateral tract, though it may affect both. Usually the asymmetry is due rather to a unilateral excess in the decussation than to an excess in the total number of fibres. Occasionally a part of the fibres of the pyramidal tract descends at the junction of the anterior and lateral funiculi.

The pyramidal tracts in monkeys appear to have similar relations to those met with in man, uncrossed and crossed fibres being present in the lateral and anterior funiculi. The same is true of the dog, though only a few fibres run in the anterior funiculus, the pyramidal tract being situated almost entirely in the lateral funiculus in this animal. In the rabbit the pyramidal tract is nearly all a crossed tract running in the opposite lateral funiculus. In rats and mice the pyramidal fibres form a definite bundle which runs almost exclusively in the anterior part of the opposite posterior funiculus. Even marsupials have a well marked pyramidal decussation, the majority of the fibres descending in the opposite lateral funiculus. Whether birds possess a pyramidal tract corresponding to that of mammals or not, is still in dispute. Reptiles, amphibia, and fish seem to be devoid of pyramidal tracts—that is, of cortico-spinal motor tracts—though all vertebrates may have a path for throwing the spinal movements under the domain of consciousness.

An examination of the fibres of the pyramidal tracts in the spinal cord shows that a majority of the fibres are fine in calibre, though there are some coarser fibres mixed among the finer fibres. The large fibres of the direct cerebellar tract stand out in marked contrast with the fine fibres of the pyramidal tract. The lateral pyramidal tract (*fasciculus cerebrospinalis lateralis*) in human beings lies always in the posterior part of the lateral funiculus. It rarely goes farther forward than the continuation of a line drawn through the two lateral horns (Flechsig). The relation to the periphery varies in different parts of the cord. At the level of the first cervical segment the area of the pyramidal tract nowhere reaches the periphery. At the level of the second and third cervical segments the area touches the periphery just lateralward from Lissauer's fasciculus. In the cervical enlargement the tract is again separated from the periphery. As the thoracic cord is descended the fasciculus approaches the periphery gradually, the posterior part reaching the surface first, the anterior part last. Below the thoracic cord, the whole lateral margin of the tract lies upon the periphery, there being no direct cerebellar tract below that level. The shape of the cross-section of the tract varies as the cord is descended. The lateral pyramidal tract usually disappears at the level of the Nn. sacrales III. and IV.

The anterior pyramidal tract (*fasciculus cerebrospinalis anterior*) is situated in the medial portion of the funiculus anterior. As was pointed out above, it varies greatly in size, and, corresponding to this variation, it sometimes occupies the whole medial margin of the anterior funiculus; in other cases only the middle or posterior portion of the same. It usually terminates below in the middle of the thoracic cord, but may end as high up as the intumescentia cervicalis, or extend as low down as the middle of the intumescentia lumbalis; in one instance even as far as the conus medullaris.

The fibres of the pyramidal tract end by running into the gray matter, not in bundles but usually as individual fibres, or small groups of fibres. Studies by Golgi's method make it seem probable that the terminals come into relation with the cells of the anterior horn, though their exact pericellular relations are yet to be worked out. Von Monakow believes that at least a part of the fibres end in the formatio reticularis, and that dendraxones (Golgi cells of type II.) are intercalated between the terminals of the pyramidal tract fibres and the cell bodies of the lower motor neurones. Rothmann maintains that the fibres of the pyramidal tract very quickly lose their myeline sheaths on entering the anterior horn, and suggests that this accounts for the difficulty in following them to their termination by Marchi's method in experimental degenerations. Campbell has followed terminals of the pyramidal tract into the gray matter, however, by the method of Marchi. The assumption that many of the fibres of the lateral pyramidal tract do not end in the anterior horn of the same side, but pass through the commissure to end in the gray matter of the opposite side (that is, that the fibres recross), has no strong support. As has been said, at least the majority of the fibres of the anterior pyramidal tract end in the anterior horn of the same side, though some appear to pass through the commissura anterior alba to end in the anterior horn of the opposite side (Hoche).

C. Spinopetal Neurone Systems Other than those whose Axones Belong to the Pyramidal Tracts.

Of late years a great deal of attention has been paid to the centrifugal spinopetal paths other than those corresponding to the pyramidal tracts. Among these there have been described: (1) a neurone system from the thalamus to the cord (thalamospinal neurone system); (2) a rubrospinal neurone system with cell bodies in the red nucleus, the medullated axones of which go to the lateral funiculus of the opposite side of the cord (von Monakow's bundle); (3) a neurone system with cell bodies in the mesencephalon with medullated axones extending to the cord (mesencephalospinal neurone system); (4) a neurone system with cell bodies in the nuclei pontis and nuclei arcuati with medullated axones extending into the cord (pontospinal or metencephalospinal neurone system); (5) neurone systems from the formatio reticularis and nuclei laterales of the medulla oblongata to the lateral funiculi of the spinal cord (myelencephalospinal neurone systems); (6) a neurone system extending from the inferior olivary nucleus to the cord (olivospinal neurone system); (7) a neurone system the cell bodies of which are situated in the nucleus nervi vestibuli lateralis (Deiters'), the medullated axones going to the spinal cord (vestibulospinal neurone system); (8) various neurone systems with cells in the cerebellum and medullated axones going to the lateral and anterior funiculi of the cord (cerebellospinal neurone systems).

(1) *Thalamospinal Neurone System.*—Such a neurone system has for a long time been postulated. Meynert believed that many of the spinopetal funicular fibres arose in the thalamus, but the investigations which have been made since his time are conflicting. Meynert believed that the portion of the anterior funiculus of the cord, immediately adjacent to the anterior horn, came from the thalamus, but Redlich has destroyed the thalamus in animals and has studied human cases in which the thalamus was extensively diseased, but could obtain no evidence of the existence of thalamospinal fibres. It is still believed, however, by von Bechterew that fibres extend from the thalamus into the fasciculus lateralis proprius of the cord (*Seitenstrangreste*).

(2) *Rubrospinal Neurone System.*—Bouchard as early as 1866 drew attention to the fact that there was a distinct difference between the descending degenerations of the lateral funiculus in brain lesions and that in spinal-cord lesions, the latter being the more extensive. This indicated the presence of spinopetal fibres in the lateral funiculus other than the pyramidal tracts from the pallium. It was later shown, especially by experiments upon dogs, that the place of the pyramidal tracts could be taken in a functional way by these paths, especially by the one extending from the red nucleus and running in the lateral funiculus along with the pyramidal tract. This bundle of fibres, designated by von Monakow as the aberrant bundle of the lateral funiculus (*aberrierendes Seitenstrangbündel*), is usually referred to in the literature as von Monakow's bundle, sometimes as the "tractus tegmentospinalis." This neurone system has been studied by Held in the human fœtus, by Boyce in the cat, by Probst in dogs, by Russell and by Rothmann in monkeys. The medullated axones arise from cell bodies in the nucleus ruber, pass through the ventral decussation of Forel in the tegmentum, pass just medial from the lateral lemniscus and lower down between the superior olivary nucleus and the tractus spinalis nervi trigemini. In the medulla the fibres appear to be mixed up with those of Gowers' tract. In the lateral funiculus of the spinal cord these fibres assume in the cross-section the form of a comma, lying medial from the direct cerebellar tract, in the lateral and ventral part of the area corresponding to the lateral pyramidal tract. Some of the fibres extend into the lowermost part of the cord. It is this fibre system that appears to be able at times to replace the function of the pyramidal tract. It is the subcortical regulator of the movements of the extremities. It itself is under the influence of the cerebellifugal fibres of the brachium conjunctivum.

(3) *Mesencephalospinal Neurone Systems.*—Certain cell bodies in the middle and deep gray matter of the superior funiculus of the corpora quadrigemina (chiefly the nucleus centralis superior and the nucleus lateralis superior) give off medullated axones which run down in the funiculus anterior of the spinal cord. The medullated axones of this tract run through the dorsal decussation

of the tegmentum (*fontaineartige Haubenkreuzung* of Meynert), and having crossed the raphe lie in a separate bundle (in the cat), which runs just ventral from the fasciculus longitudinalis medialis, and is called by Tschermak the "predorsal longitudinal bundle." In human beings the fibres are probably mixed with those of the fasciculus longitudinalis medialis. Collaterals are given off to the eye muscle nuclei and to the gray matter of the formatio reticularis, but the main bundle runs down in the cord, where it occupies the anterior part of the fissural portion of the anterior funiculus. It becomes exhausted by giving off collaterals and terminals to the anterior horn of the same side, and partly by sending axones through the anterior white commissure to the contralateral anterior horn. Some of the fibres extend down as far as the lower part of the lumbar cord. It seems very probable that a part at least of Loewenthal's marginal fasciculus is identical with this system of fibres.

(4) *Pontospinal or Metencephalospinal Neurone System, and* (5) *Myelencephalospinal Neurone System.*—In the medulla and pons are situated groups of perikaryons which give off axones that run down to the spinal cord. Most of these are as yet very imperfectly understood. There is evidence, however, that some of the cells of the nuclei pontis and of the nuclei arcuati give off such axones. If so, we are justified in speaking of pontospinal neurone systems. A good deal of work has been done upon the descending fibre systems in the formatio reticularis—fibre systems which have their origin in perikaryons of the formatio reticularis grisea, specially in the inferior, middle, and superior central and lateral nuclei. Axones from the cells of the nucleus centralis medius run downward in the fasciculus longitudinalis medialis to reach the anterior funiculus of the cord, where they run close to the fissura mediana anterior. This is an uncrossed descending spinal neurone system from the formatio reticularis. Another fibre system from the central nucleus descends in the opposite lateral funiculus of the spinal cord occupying an area in the dorso-lateral region of the lateral pyramidal tract, medial from the rubrospinal fibre system and the direct cerebellar tract.

(6) *Olivospinal Neurone System.*—I have fully described this system on pages 954–958 of my book on "The Nervous System." The fibre system is usually known as Helweg's path, though it was described earlier by Paul Meyer. Its development has been studied by von Bechterew, who designates it the *Olivenstrang*. The path is seen as a triangular area in cross-section; hence Helweg's term (*Dreikantenbahn*). The cells of origin may be in the inferior olivary nucleus, or they may come from higher regions. Golgi studies are still lacking except for meagre statements in von Kölliker's text-book.

(7) *Vestibulospinal Neurone Systems.*—The cell bodies which give rise to the medullated axones of this path are situated chiefly in the nucleus nervi vestibuli lateralis (Deiters), though some of them may be situated in the nucleus nervi vestibuli superior of von Bechterew. The axones pass ventralward from Deiters' nucleus into the formatio reticularis alba and descend. On their way down they pass through the area situated between the nuclei laterales and the remains of the anterior horn. In the spinal cord they lie in the peripheral parts of the zone of exit of the anterior root fibres, and in the lateral portion of the funiculus anterior. Some of the fibres of this system descend as far as the lumbar cord. The axones appear to terminate by running in to end among the cells of the anterior horn of the same side. This neurone system is under the influence of impulses from the vestibular nerve on the one side and from the cerebellum (nucleus fastigii) on the other. Its influence on the cord is probably concerned with the coordination of the axis of the body and orientation in space.

(8) *Cerebellospinal Neurone System.*—Though a vast amount of work has been done with the idea of determining the fibre systems which throw the spinal cord directly under the domain of the cerebellum without the intermediation of any relay station, it must be confessed that our knowledge upon this subject is still, in reality, most meagre. Marchi early described a fibre system in the spinal cord which degenerated after removal of the cerebellar hemisphere. He thought that the fibres came chiefly from the vermis, partly from the hemisphere, that they passed through the brachium pontis, and then by way of the ground bundles into the anterior and lateral funiculi of the cord. He could follow the degeneration throughout the whole length of the cord. In cross-sections this degeneration occupied two areas, one extending along the periphery of the cord from the fissura mediana anterior to the anterior extremity of the direct cerebellar tract, that is, in an area corresponding to the *zone sulcomarginale* of Marie; the other, a more lateral area, situated just in front of the lateral pyramidal tract. It was his opinion that the fibres ran in to end in the anterior horn of the spinal cord. This degeneration, described by Marchi, probably corresponds, at least in part, to the so-called cerebellar tract of Loewenthal.

Ferrier and Turner dispute Marchi's conclusions, inasmuch as they found that when one hemisphere of the cerebellum is extirpated without injury to neighboring parts, no degeneration can be traced to the cord, though degenerated fibres can be followed through the corpus restiforme to the inferior olivary nuclei and the nuclei of the posterior funiculi. When the vermis is extirpated alone, the fibres which run to the nucleus nervi vestibuli lateralis of Deiters degenerate. It is their opinion that the degeneration, described by Marchi, occurs only when Deiters' nucleus is injured in the attempt at cerebellar extirpation. This view is supported also by the experimental work of Risien Russell and by that of Mott.

Marchi has, however, found a supporter in Biedl, who reproduced a degeneration of the fibre systems, described by Marchi, by cutting the corpus restiforme. He thinks, however, that Marchi's tract reaches the cord by way of the inferior cerebellar peduncle rather than by way of the middle cerebellar peduncle, as Marchi asserted.

The experimental work of Thomas tends to support Marchi's observation as far as the fibres in the anterior funiculus are concerned. He thinks that the fibres arise from cells in the nucleus dentatus, and that they pass through the superior vestibular nucleus of von Bechterew and the lateral vestibular nucleus of Deiters into the formatio reticularis, and thence into the anterior and lateral funiculus of the cord. His work was done chiefly upon dogs. Extirpation of the cortex of the cerebellum alone does not cause the degeneration; it is necessary to injure the nucleus dentatus cerebelli. If Deiters' and Bechterew's nuclei are also injured, the degeneration in the cord is much more extensive.

Ramón y Cajal has made an important contribution to the neurone system under discussion by the application of Golgi's method. He finds that the axones of the cells in the nucleus dentatus, passing out in the brachium conjunctivum, give off descending limbs of bifurcation which run to the anterolateral fasciculus of the cord. In his opinion it is these axones which correspond to the descending cerebellar path of Marchi. Ramón y Cajal emphasizes the fact that in frontal sections of the guinea-pig's brain, stained by the method of Weigert-Pal, this cerebellospinal path from the brachium conjunctivum can be clearly seen as isolated bundles. (See Fig. 439 on page 430 of his "Histologia del Sistema Nervioso de los Vertebrados.")

It may be regarded as certain, therefore, that a direct uncrossed cerebrospinal neurone system exists, the cell bodies of which are situated in the nucleus dentatus (and perhaps in the neighboring gray nuclei), the medullated axones of which go through the anterolateral white matter to the anterior horn of the cord. It would appear, too, that the fibre system, making up the spinal portion of this path, or a part of it, is really an offshoot or by-path from the main ascending fibre system of the brachium conjunctivum. The function of the path is doubtless coordinative. It seems probable that it carries to the anterior horn cells at least a part of those cerebellar impulses which maintain the equilibrium of the body.

LEWELLYS F. BARKER.

SPINAL-CORD DISEASES: ACUTE ASCENDING PARALYSIS.—(Synonym: Landry's Paralysis.) In 1859 Landry described the symptom complex which has since then been known both as Landry's paralysis and as acute ascending palsy. The clinical picture he portrayed was the following: The sudden development in a previously healthy individual of a flaccid paralysis of the legs, which generally began first in one and then within a few hours or a day affected the other. When the paralysis of the legs had become complete, the trunk muscles became paralyzed, and then in the space of a few days the arms were involved in like manner. Next there was involvement of the deglutition, articulation, and respiratory musculature, and in a short time death followed from asphyxiation. There are milder cases, however, in which there is restitution of function. Landry described prodromes, such as general malaise and paræsthesia in the extremities, and during the course of the illness slight disturbances of sensation. He laid particular stress on the absence of muscular atrophy, the presence of normal electrical reactions, and negative findings at the autopsies.

Since Landry's original cases were published, many cases, either similar to his or varying from the type in one essential or another, have been reported, until to-day our conception of the disease has broadened so as to include cases exhibiting a wider range of symptoms; so that, as Oppenheim says, the only essential symptom necessary to the disease is the rapid development of a flaccid paralysis, commencing in the lower extremities and affecting successively the arm and the bulbar nerves, though in rare cases the order of involvement is reversed.* In the literature under this heading have been included many cases which undoubtedly belong to other diseases, principally acute anterior poliomyelitis and multiple neuritis.

ETIOLOGY.—The disease is rather uncommon in its occurrence. Men are affected more often than women, and as a rule between the ages of twenty and forty, though instances of its occurrence in children and old people have been observed.

The view most generally held as to the etiological factor of the disease is that it is due either to some form of toxæmia or to bacterial infection. Landry himself was under the impression that it was caused by poisoning, and this opinion was accepted by many subsequent observers, but especially by Westphal. The following facts Diller regards as pointing in this direction: First, the presence in some cases of enlargement of the spleen and lymph glands, hemorrhagic spots in the lungs and intestines, and albuminuria; second, the finding of bacteria in some of the cases. The varieties found include anthrax, typhoid, and other unclassified bacilli, streptococcus, varieties of staphylococci, diplococci, and the Fränkel pneumococcus. No specific form of micro-organism has been isolated, but the disease seems to be capable of development after diphtheria, typhoid, variola, anthrax, pneumonia, pertussis, the puerperium, malaria, and probably also upon septicæmia as a basis. Oppenheim thinks it doubtful whether the entrance of the micro-organisms themselves into the spinal cord, medulla, and peripheral nerves can produce the disease, but he believes that probably their toxins injure the motor tracts in such a manner as to cause paralysis, without as a rule producing recognizable lesions. Thoinot and Masseline and Remlinger have produced in rabbits symptoms similar to Landry's paralysis by the injection of micro-organisms into the circulation.

* In recent years some authors have regarded Landry's paralysis as being merely a symptom complex due to various causes and not a disease or clinical entity with a definite pathological basis.

One case has been reported in which the disease followed a kick from a horse affected with septicæmia.

Alcohol has been mentioned as an etiological factor in some cases, and exposure to cold and overexertion likewise. Syphilis was formerly regarded as being a not uncommon cause of the disease, though if the question be looked at in the light of our present knowledge of syphilis and its pathology, it seems highly improbable, as Nonné points out, that it could cause the paralysis and yet leave no evident lesion.

Pathological Anatomy.—Landry postulated as one of the characteristics of acute ascending paralysis the absence of any lesion in the spinal cord, and as a matter of fact in many of the earlier reported cases no changes were found. Since then, however, through our better technique and in the light of our greater knowledge of the nervous system and its pathology, morbid changes in the spinal cord have been found in many cases. The lesions reported are very numerous and varied in their nature, and do not show any considerable uniformity. Disseminated areas of inflammation have been observed in the medulla oblongata by Omerod and Prince, while Eisenlohr, Schultze, Ketli, and others have found similar changes in the spinal cord. In some cases the axis-cylinder processes in the antero lateral columns of the cord were swollen; in others there were changes of varying intensity in the anterior horns, similar to those found in poliomyelitis. One case showed only a degeneration in the anterior roots, while in another there was a focus of myelitis.

In addition to these changes in the cord itself the peripheral nerves have been found to be affected. Sometimes the peripheral neuritis has been the only lesion found, and this has led one set of observers (Dejerine, Barth, Ross, Putnam, and others) to regard it as the characteristic morbid condition of Landry's palsy. They explain the alterations in the anterior horn cells, when they occur in conjunction with peripheral neuritis, as due to trophic disturbances. Dejerine and Thomas, in their recent work on spinal-cord diseases, go so far as to say that it is a disease of the peripheral neurones, and is poliomyelitis when the cell body is affected and polyneuritis when the axis-cylinder processes are implicated. Diller states, as an argument against this theory, that the cases in which there is no peripheral neuritis are frequent, and that the changes found in the nerves are usually those of degeneration, not of inflammation.

The spleen is usually acutely enlarged, the lymphatic glands swollen, and in some cases there is acute degeneration of the viscera.

Oppenheim sums up our knowledge of the pathology of Landry's paralysis by saying that the changes in the spinal cord, especially in its gray matter, are the predominant ones; and that they sometimes consist of inflammatory conditions and vascular disturbances (disease of vessels, hemorrhage, exudation, thrombosis, softening, and infiltration); sometimes of changes in the nerve cells, as described by Marinesco and by Bailey and Ewing.

Symptomatology.—The disease commences suddenly with paralysis of the extremities, or it is preceded by prodromes. These latter consist of a chill or chilly sensations, slight fever, pain in the back and in the extremities, and paræsthesia, more rarely hyperæsthesia and general malaise.

Pain and general weakness may occur fully a month before the actual onset of the disease. The paresthesia is usually in the fingers or toes, and may be very marked and distressing.

The *paralysis* as a rule marks the beginning of the disease. It is generally ascending in type, that is, it affects the lower extremities first. The feet are first affected, either both at once or successively. Then the legs, thighs, the lumbar, abdominal, and chest muscles are successively involved; next in order are the muscles of the hand, forearm, and arm, then those of the neck, and finally there occurs paralysis of the muscles innervated by the bulbar nerves, viz., those of speech, deglutition, and respiration.

The paralysis manifests itself first as a weakness in one or both legs, then becomes complete and flaccid, there being no spastic phenomena. The paraplegia can develop in a day, and the involvement of the other muscles takes place within eight or ten days, rarely in three or four.

Cases have been described in which there has been a descending paralysis, and also all four extremities have been affected at the same time. These cases are rare. Westphal reported a case in which only bulbar symptoms appeared. Cases have been reported in which the cranial nerves were involved, the paralysis affecting the muscles controlled by the facial, the eye muscles and those of accommodation; as a rule, however, these nerves are not involved. The pulse rate is usually increased in frequency because of the affection of the vagus, and attacks of asphyxia due to paralysis of the respiratory muscles cause death.

The *electrical reaction* is generally prompt and normal, especially in those cases which run a short course. Sometimes there are quantitative variations in the electrical reaction, and the reaction of degeneration has also occurred. Oppenheim noted the following peculiar electric reaction in one of his cases: it was impossible to increase the intensity of contractions by increasing the strength of the current used. Examination of a piece of this muscle showed waxy degeneration.

The absence of muscular atrophy * was regarded as one of the characteristics of the disease, and in the majority of cases this holds true. Some authors have regarded its development in the later stages of the disease, when it runs a protracted course, as being due to inactivity. But there have been undoubted cases of Landry's paralysis in which the wasting of the muscles was an early occurrence. Fibrillary twitchings are sometimes seen.

Sensibility is usually but slightly disturbed. Landry described the presence of slight changes. Bailey and Ewing describe thirteen cases of sensory involvement out of the forty-four genuine cases which they found in literature up to 1896. As a rule, marked disturbance is absent. Hypæsthesia in the extremities, and more rarely hyperæsthesia, have been described. In some instances delayed transmission of pain or temperature sense, or failure to discriminate between pain and touch sense, and diminution in the acuteness of the muscular sense, have been observed. Trophic disturbances are not present.

Patellar and superficial reflexes are lost, though they may be present for some time in the early stages of the disease. As a rule the bladder and rectum are unaffected. Cases have been reported in which either one of the sphincters has been weakened or paralyzed. Sometimes at the onset there may be temporary retention of urine, or later, when the abdominal muscles are paralyzed, there may be constipation.

It is characteristic of Landry's paralysis that there is either no rise of temperature, or only a very slight rise, throughout the course of the disease. Regarding this, again, exceptions have been reported. Sweating is said by some to occur frequently. Albuminuria generally occurs, and in one case there was hæmatoporphyruria.

The sensorium remains almost invariably clear until the end. Delirium has been present in those cases which have fever.

Prognosis.—The prognosis is grave. Most of the cases end fatally. The disease may terminate abruptly at the end of two or three days, death being due to bulbar paralysis; as a rule, however, the duration of the disease is prolonged to eight days before the onset of bulbar symptoms. The disease may assume a subacute character and last for two months or more. Some of the cases have terminated in complete or partial recovery. Oppenheim regards it as a sign of favorable outcome when there is a remission in the bulbar symptoms. Generally the paralysis first disappears in the part which was

* What has been said of the electrical reaction can with equal truth be said of the occurrence of muscular atrophy.

first affected. Convalescence may last for many months. Remissions and relapses with a fatal termination are possible.

Therapy.—There is no therapeutic agent which is specific in its action. The application of the actual cautery to the back has been recommended. In cases in which syphilis is suspected vigorous mercurial and iodide treatment should be used. Electricity, especially galvanism, has been used. The chief attention of the physician should be directed to the nourishment and stimulation of the patient during the acute stage; and then, if he survive, an effort should be made to restore the functions of the paralyzed parts by means of hydrotherapy, massage, electricity, nutritious food, change of scenery, etc.

Israel Strauss.

SPINAL-CORD DISEASES: ACUTE SPINAL MENINGITIS.—The membranes of the spinal cord consist of an outer dense fibrous sheath, the dura mater, and an inner delicate vascular sheath, the pia mater. The web-like fibres connecting these two, and known as the arachnoid, may be conveniently reckoned together with the pia mater. The spinal dura is not adherent to the inner surface of the bones forming the vertebral canal. Between the periosteum and this membrane is a loose connective tissue of interlaced bundles with delicate slender elastic fibres and spindle-shaped connective-tissue cells, and within the meshes of this tissue there is a greater or less amount of fat, which is often gelatinous in appearance. The dura mater itself is a dense white sheath composed of bundles of white fibrous and of elastic tissue in about equal numbers, running lengthwise. Both outer and inner surfaces are covered with endothelium, and between the meshes are lymph spaces which open upon these surfaces, thus establishing a connection between the outer surface of the dura and the space between dura and pia. Binding the dura to the pia mater are the delicate fibres which form the arachnoid, fibres of connective tissue bound together into lamellæ surrounded by very fine elastic fibres and covered with endothelial cells. The outer layer of the pia is of the same structure as the arachnoid, the inner is separated from this by the pial capillaries and vessels, which, surrounded by prolongations of the fibrous and elastic reticulum composing the inner layer, pass into the substance of the cord. Golden-brown pigment cells with branching processes are found in this layer, especially in the cervical region, where they may lend a brown color to the membrane. Both membranes are supplied with nerves, the pia more abundantly. The lymphatics of the pia are continuous with those of the cord.

The inflammation of the membranes of the cord may affect the outer membrane, the inner, or both. Internal meningitis, or leptomeningitis, always extends to the arachnoid also, although an effort has been made by some authors to distinguish a pure arachnitis, so called, without involvement of the pia. External meningitis or pachymeningitis also usually extends to the pia-arachnoid, at least in acute inflammations; the chronic processes may remain limited to one or the other. As the symptoms in all forms of acute meningitis are very similar and certain symptoms are common to all, it will simplify matters to describe first in full detail the symptoms of the typical variety, acute purulent leptomeningitis, and then, in the less important varieties, the symptoms will not need to be described in full again.

I. *Acute purulent leptomeningitis, acute cerebro-spinal meningitis, acute cerebro-spinal fever, epidemic cerebro-spinal meningitis.*

A. Hirsch has given an excellent historical survey of this disease ("Die Meningitis Cerebro-spin. epidemica," Berlin, 1866). The first well-authenticated epidemic appeared in France among the soldiers of the army in 1805, and was followed by sixty-two epidemics in that country, forty-eight of which began in the army. The disease first appeared in epidemic form in the United States probably in 1806, and from then on until 1830 there were frequent outbreaks in this country, and seven years later in France again, then throughout Europe. The latest epidemic which has been carefully studied was that in Boston in 1896-97, to the report of which by Councilman, Mallory, and Wright we shall have occasion to refer frequently. The later epidemics have usually been less severe than the earlier, and show less tendency to develop among the standing armies.

Winter and spring seem the seasons most favorable for the development of an epidemic. It is not a disease of cities; some of the severest epidemics have been in country districts. Children are not as susceptible as young adults; the disease is rare before the first year. The mode in which infection takes place is not known; but the nasopharyngeal passage is supposed to be the place of entrance for the micro-organisms. Apparently it is not contagious, for it is rare to find more than one case in the same family. Insanitary surroundings, overcrowding, exhausting exertion, exposure, etc., seem to aid in its spread. There are isolated sporadic cases, probably of the same character as those occurring in the course of epidemics, which are scattered along in the intervals between outbreaks.

Bacteriology.—The causative agent of cerebro-spinal meningitis is still in question. The diplococcus intracellularis meningitidis or meningococcus intracellularis of Weichselbaum, the pneumococcus of Fraenkel, the streptococcus meningitidis of Bonome the meningococcus of Foà, the streptococcus pyogenes and the staphylococcus pyogenes, have all been isolated by different observers. The colon bacillus has been stated to be the etiological factor in cerebro-spinal meningitis of the new-born.

Weichselbaum found the organism which bears his name in six out of eight cases examined by him in 1887. These six cases were all primary. In the other two cases, which were secondary to pneumonia, he isolated the pneumococcus only. His results, corroborated by Goldschmidt and by Edler, were more strongly confirmed by Jäger, who, in 1895, found the organism in twelve cases during an epidemic. Councilman also looks upon the diplococcus intracellularis as the cause of the epidemic form, and lays great stress on this fact from the point of view of both diagnosis and prognosis, inasmuch as, in his opinion, all cases are fatal except those caused by this diplococcus. When the pneumococcus or the streptococcus was found there was associated with the meningitis some other lesion, in lungs or heart usually, and none of these cases recovered. Sporadic cases are probably not caused by the Weichselbaum organism. Councilman's conclusions are based upon the largest number of bacteriological examinations ever made by one observer —thirty-eight positive results from fifty-five lumbar punctures, thirty-one positive results from thirty-five autopsies.

On the other hand, Fraenkel isolated the pneumococcus which bears his name from the pia-arachnoid in spinal meningitis, and his results have been confirmed many times. Wolff claims that it is present in forty-two per cent. of all cases. Flexner and Barker found this organism during the Maryland epidemic of 1892.

The streptococcus has been isolated, and in other cases the staphylococcus pyogenes also. Among some bacteriologists (as Bordoni-Uffreduzzi) the opinion prevails that all of these different cocci are varieties of the same organism—the pneumococcus of Fraenkel.

The pathology of cerebro-spinal meningitis is that of an extensive purulent inflammation, with infiltration of the subarachnoid space. The cerebro-spinal fluid is increased and usually turbid with floccules of fibrin in the early stages; later on, it becomes purulent. This increase in the fluid causes bulging of the dura, especially posteriorly, perhaps because of the patient's recumbent position. The fluid, according to Councilman, contains many leucocytes, but not abundant fibrin except in the cases caused by the pneumococcus. Flexner found numerous large phagocytic cells in the fluid from one of his cases. The small pial vessels are enormously distended, the leucocytes being collected along their walls and in the perivascular lymph spaces. The inner surface of the dura is reddened, and the inflammation may extend along the sheaths of the nerves and into the substance of the cord, although there are cases in which, with extensive involvement of the pia-arachnoid, the cord escapes completely. Usually there is a perivascular infiltration with leucocytes and phagocytic cells, and a swelling and proliferation of the cells of the neuroglia. Klebs, Zenker, Strümpell, and Barker all describe accumulations of leucocytes in the cord, forming in some cases focal abscesses. The changes in the nerve cells, shown by the Nissl stain, are peripheral chromatolysis—characteristic of all toxic conditions—and central chromatolysis—characteristic of injury to the axone of the cell. Sections treated by Marchi's method may show degenerated fibres, especially in cases of long duration.

Congestion and œdema of the lungs is a frequent complication. Pneumonia, either primary or secondary, and usually lobular, is also frequently present. Councilman found in one case that the process in the lung was due to a purulent embolus from the meninges lodging in a small branch of the pulmonary artery. The liver and kidneys usually show only acute parenchymatous degeneration, the intestinal tract is usually not affected, but may show swelling of the follicles, and the spleen is only exceptionally enlarged. Endocarditis and pericarditis may be complications.

Symptoms.—There is seldom any real prodromal stage, though there may be one or two days of languor, headache, and slight chills preceding the onset of the disease. Usually this is sudden, ushered in by a severe chill followed by fever, vomiting, and headache. The course of the disease is so irregular that it is hard to give a description of a typical form, harder still to divide it into definite stages or definite varieties. Hirsch's classification into three forms, the malignant ("foudroyante"), the abortive, and the acute and subacute, is perhaps the simplest. The malignant form is characterized by its sudden onset, usually in a healthy person, and rapid development. Within a few hours vomiting, delirium, convulsions, rigidity of the neck, unconsciousness, and collapse may follow each other in rapid succession, and death has been known to take place in less than twelve hours. Several cases of less than twenty-four hours' duration are on record. These cases belong not to the sporadic but to the epidemic form, and are more apt to occur among the early than the later cases. A purpuric rash is often seen, which has led to the clinical names applied to this disease: "spotted fever," "malignant purpuric fever," etc. The second, abortive, form would be recognized with difficulty in the absence of an epidemic. More or less pronounced cervical rigidity with pain on motion, and severe, remitting headache may be the only symptoms present. It is apt to last only a few days, but there may be recurrences of rigidity and headache for some time afterward.

The third is the ordinary form, which usually begins more or less suddenly with headache, generally frontal and very severe. Vomiting is often an early symptom and a valuable aid in diagnosis. A more or less pronounced chill is followed by a rise of temperature to 101° or 102° F. The headache often increases in intensity, rendering the patient delirious, not from the meningitis but from the extreme pain. This is not, however, a gauge for the severity of the disease, for it may be very severe in patients who make a good recovery. It is subject to remissions and is apt to come on suddenly during sleep, making the patient waken with a sudden cry ("cri hydrocephalique"). The vomiting may return with the exacerbations of pain; usually it lessens as the disease progresses, but may be so persistent as to endanger the patient's life through excessive weakness. Dizziness, restlessness, sensitiveness to light and sound accompany the headache.

Rigidity of the neck is an early and important symptom, perhaps the most constantly present symptom of this disease. It consists of a tonic contraction, reflex, of the deep muscles of the neck, especially the splenius, is increased on active or passive attempts at movement, and is accompanied with pain. In some cases the rigidity is so pronounced that by putting the hand under the patient's head his body may be raised from the bed without making the neck bend. Often the head is bent back, sometimes so far that the occiput lies between the shoulder blades. The rigidity does not, however, affect the side movements of the head. The pain may be constant, even more severe than the headache, or may be absent when the patient is perfectly quiet and there is no pressure on the neck.

There are also pain and sometimes rigidity all along the spine, increased on motion and pressure, and there may be lightning pains in the limbs due to irritation of the peripheral nerves. Flattening or retraction of the abdomen is not so frequent as in tuberculous meningitis. Traube has pointed out that it is due to a drawing together of the intestines from irritation of the vagus—which is also responsible for the vomiting—and not, as many suppose, to a contraction of the abdominal muscles. Constipation from tonic contraction of the bowels may persist throughout the attack; diarrhœa is rare.

Hyperæsthetic areas alternating with areas of normal sensation are most frequent over the lower extremities and involve both skin and muscles. In some cases this symptom is very pronounced, and even in deep stupor a reaction may be obtained by pressing the muscles of the legs. Anæsthesia is more apt to be a sequela.

The motor disturbances consist in the rigidity of neck and back already described, in tremors or even spasms of the muscles of arms or legs, occasionally of the face, in strabismus, difficulty in swallowing, and sometimes even trismus. Kernig's symptom is often present—a strong flexion of the knee caused by passive flexion of the thigh upon the abdomen. The patellar reflex may be increased or completely lost. Later on, these irritative symptoms may be succeeded by symptoms of paresis, though the latter more often appear as sequelæ. The most common forms are ptosis, dilated pupils, strabismus divergens, and paralysis of the facial muscles; much less common is hemi- or paraplegia.

The cerebral symptoms begin as delirium, passing into stupor or even coma. In less severe cases without delirium there are insomnia, restlessness, and irritability, confusion, dulness or excitability, perhaps hallucinations. Stupor is regarded as a serious symptom, being present almost always in the fulminating cases. The temperature curve is very irregular. In the very rapid cases it soon reaches a high point, 105°–106° F., and remains there for several days, either rising to hyperpyrexia (108°) just before death, or falling suddenly. In the more usual forms the temperature begins to sink after a few days and is then irregularly remitting, showing a great range within twenty-four hours, high fever, and entire absence of fever. Usually the febrile exacerbations tend to be less severe as the disease progresses, but this is not invariably true, and every rise of temperature must be regarded as serious. In atypical cases a regularly remitting fever with chills may simulate malaria; in others there may be a crisis on any day between the sixth and the tenth.

The pulse is usually rapid, especially in children. A very slow pulse is rare. In collapse the pulse is small and extremely rapid from involvement of the vagus, a serious symptom in adults. Heart complications are rare. The respirations may be increased in frequency, but are regular in ordinary cases. Irregular respiration is a graver symptom in adults than in children. In some instances there may be typical Cheyne-Stokes breathing.

The skin symptoms are very variable. Petechiæ seem to have been common enough, in the early epidemics, to give the disease the name of spotted fever, but in many of the later ones this symptom has been insignificant or absent. Roseolæ, like those of typhoid, scarlatinal eruptions, erysipelatous eruptions, urticaria, erythema nodosum, even gangrene, have been observed. Herpes is present in the majority of cases, and is an important diagnostic symptom. It appears most commonly between the third and sixth days, on lips, nose, and cheeks; more rarely on the neck and body.

The urine is apt to be increased, often contains albumin, sometimes sugar. The diazo reaction is usually present.

Involvement of the special senses constitutes a grave complication. There may be complete loss of smell and taste. In the case of the ear the deafness resulting from inflammation of the labyrinth or from otitis media is apt to be persistent, and in young children results in deaf mutism. Moos found thirty-five cases of deafness out of sixty-four cases of recovery from meningitis. There may be keratitis or even panophthalmitis from an extension of the inflammation along the sheath of the optic nerve, which may itself show an acute neuritis. Randolph examined forty cases in the Maryland epidemic of 1892, and found the fundus normal in only seven. Most of these thirty-three showed a venous congestion of the disc with remarkable tortuosity of the vessels, which sometimes looked quite black as if from complete stasis. Six cases had neuritis optica, one an acute retinitis. The right eye was by far the most frequently affected. The pupils are usually small at first, then there is often a unilateral dilatation, which is a valuable aid in diagnosis. As a rule, just before death there is extreme dilatation of both pupils.

Complications in the form of joint affections have appeared in certain epidemics: serous effusion into knees, ankles, and wrists. More rarely the exudation is purulent.

There is a question as to whether the pneumonia so often accompanying meningitis is to be regarded as a cause, a complication, or a sequela. Many observers have considered the meningitis as secondary to the pneumonia. In some cases this is indubitably true, the inflammation being caused by an invasion of the meninges by the pneumococcus; in other cases there has seemed to be a double infection, and finally Councilman declares the pneumonia, in the epidemic forms at least, to be secondary to the meningitis and caused by the entry of the diplococcus intracellularis into the lungs. He succeeded in isolating the organism from eight cases of pneumonia complicating epidemic meningitis.

Excessive anæmia and emaciation, even in robust young patients, forms a very serious complication in the more protracted cases. When the vomiting has been obstinate or the pain persistent and exhausting, it may reach as extreme a form as that of carcinoma or phthisis (Klebs). Undoubtedly many patients die of inanition in the later weeks of the disease.

There is usually a leucocytosis which may be very pronounced, and which is an aid in the diagnosis between this disease and typhoid fever.

Sequelæ.—Headache may persist for years, caused probably by areas of thickening in the pia mater. Deafness and blindness have already been referred to as deplorably frequent sequelæ. Loss of speech, independent of loss of hearing, mental feebleness, aphasia, and loss of memory are not so persistent, but tend to pass away slowly. Hemiplegic or paraplegic symptoms, paralysis of cranial nerves, also tend to clear up.

Diagnosis.—In the absence of an epidemic this may not be easy. Any acute infectious disease in which the cerebro-spinal symptoms are pronounced may be, undoubtedly often is, mistaken for cerebro-spinal meningitis. The diagnosis between the epidemic form and the other forms of acute meningitis also presents difficulties, and is of special importance from the point of view of prognosis, for the epidemic form has the most favorable outlook. Tuberculous meningitis has a longer prodromal period, the symptoms are usually less acute, the fever not so high, and there are usually evidences of tuberculous lesions elsewhere in the body. The purulent forms due to infection by streptococcus or pneumococcus are said to be characterized by greater severity of the cerebral symptoms—delirium and coma—and by a less extreme rigidity of the neck (Leichtenstern). Quincke's lumbar puncture is a most valuable diagnostic aid. Councilman says that the bacteriological examination of the fluid withdrawn is as important a clinical procedure as examination of sputum. His results have already been quoted. Lichtheim states that he has never failed to find tubercle bacilli in all the cases of tuberculous meningitis thus examined in his clinic. The presence of streptococci has been demonstrated in many cases, and according to Councilman and to Leyden and Goldscheider, these cases invariably prove fatal. The naked eye appearance of the fluid withdrawn by puncture is also important. A large amount of fibrin indicates infection with the pneumococcus. Fluid withdrawn early in the disease is usually almost clear and contains only polymorphonuclear leucocytes; later on, epithelioid and large phagocytic cells are found (Flexner). In very rapid cases the fluid is not so abundant, and may be distinctly purulent. Lichtheim records a case in which the puncture yielded no pus, yet the patient died of secondary purulent meningitis, the pus being found in localized pockets. The puncture is best made between the second and third or third and fourth lumbar vertebræ, the needle passing in for a depth of 4 cm. in children and 7 or 8 cm. in adults. The great increase of pressure in the cerebro-spinal fluid makes aspiration usually unnecessary. It is a procedure often attended with beneficial results to the patient and seldom at all harmful. Lichtheim has, however, recorded two cases in which an exacerbation of the symptoms followed so immediately upon the puncture as to leave little room for doubt that they were caused by the puncture. Only one of the cases, however, ended fatally.

The differential diagnosis of this disease from typhoid fever depends, in cases in which the nervous symptoms are prominent, upon the great irregularity of the temperature chart in cerebro-spinal fever, the presence of herpes, the leucocytosis, and the detection of micro-organisms in the cerebro-spinal fluid.

Tetanus has symptoms of rigidity and muscular spasm much like those of the initial stages of cerebro-spinal fever, but tetanus begins without fever, trismus is an early and prominent symptom, the muscular spasms are more easily excited, the sensorium is intact, and there is absence of vomiting and headache.

Acute muscular or acute articular rheumatism, and especially rhuematism of the cervical muscles in childhood, may be hard to distinguish from meningitis, but there are no radiating pains, and the swelling of the joints in meningitis, if present, is a late symptom.

Prognosis.—The mortality from this disease is usually high, although different epidemics vary greatly in this respect. According to Hirsch, the average mortality is thirty-seven per cent. for European, forty-five per cent. for American epidemics. It is said to be higher in the small epidemics. Councilman's figures for Boston were sixty-eight per cent., Flexner's and Barker's for Maryland only forty-eight per cent. Early childhood is bad; healthy young persons have the best chance. In all cases it is extremely difficult to give a prognosis, for the disease is liable to sudden fatal exacerbations at any time; while, on the other hand, the most serious cases, even the fulminating ones, may recover. Symptoms of depression, as coma or stupor, convulsions especially in adults, obstinate vomiting, very high fever, are all grave, while a long protracted case is apt to die from inanition.

Treatment.—In the early stages cold to the head and spine by means of ice bags and the ice coil, free diaphoresis and evacuation of the bowels, and perfect quiet, are all that is indicated in uncomplicated cases. Severe pain in the head or back often requires morphine, sometimes in large doses. Chloral seems to be well borne and is preferred by some clinicians. Local blood letting by wet-cupping or leeches is said to afford relief in delirium with great congestion of the head. Bathing or cold packing or sponging is recommended by Osler, but strongly objected to by Leyden and Goldscheider, on the ground that the necessary moving increases pain and may cause unconsciousness. Counter irritation is more valuable, in the later stages, for persistent headache, and may be produced by a light application of the Paquelin cautery; blisters are no longer in favor. The same may be said for mercury, formerly so much employed. Iodide of potassium is still recommended by many writers. Landon Carter Gray advises combining it with ergot and quinine. Persistent vomiting is best treated by hypodermic injections of morphine, in cases which cannot be controlled by simpler remedies, such as iced champagne, sinapisms, etc. Surgical treatment (the removal of the arch of a vertebra, incision into the dura, and drainage) has not given encouraging results. The nutrition is of the greatest importance, especially in protracted cases. While there is still much fever, milk and broths are indicated; in the later stages and in the intervals between the exacerbations any light nutritious food may be given. Unfortunately there is often great difficulty in inducing the patient to take nourishment, and forced feeding may have to be used. As general tonics quinine in large doses, iron, the iodides, and belladonna have been recommended.

II. *Acute Secondary Leptomeningitis.*—This is distinguished from the form just described by the fact that it is secondary, not primary; according to many observers it is distinguished by the fact that it is caused by micro-organisms other than the diplococcus intracellularis Weichselbaum. These cases are very hard to distinguish from sporadic cases of cerebro spinal fever proper, cases occurring in the absence of an epidemic. Councilman makes a sharp distinction between those sporadic cases which are proven to be due to infection by Weichselbaum's meningococcus, and the secondary cases which are caused by the pneumococcus, streptococcus, etc. Osler divides the meningitides into four classes: (1) Those due to the diplococcus intracellularis; (2) those due to the pneumococcus, which are usually secondary to pneumonia; (3) those due to the tubercle bacillus; and (4) those due to the streptococcus. Under this last head would come most of the cases which are secondary to otitis media, to mastoiditis, to erysipelas, to periostitis following trauma, to septicæmia, to ulcerative endocarditis, to extension from neighboring foci of suppuration, as pelvic cellulitis, suppurative pleuritis, etc., also the cases of meningitis complicating the acute infectious diseases. Exceptionally other micro-organisms are found in these secondary cases, as the typhoid bacillus, the colon bacillus, the staphylococcus pyogenes, and the gonococcus.

The extent of the disease is very variable. The suppuration may be limited to small foci or may form a general infiltration. The pathology is that of purulent inflammation, and does not need recapitulation. An extension of the process to the dura seldom occurs; the inflammation remains limited to the pia-arachnoid.

The symptoms are those of acute cerebro-spinal meningitis, complicated by the pre-existing disease. Headache, delirium, rigidity of the neck with or without retraction, high fever, vomiting, and convulsions, when developing in the course of an acute infectious disease, as a sequence of trauma or in a general septicæmia, would indicate an extension of the infection to the cerebro-spinal membranes. There may be trismus, epileptiform attacks, hyperæsthesia of the muscles and skin, twitchings or muscular spasms. As in the epidemic form, herpes is common. The temperature varies, but is rarely as high as in the epidemic form, and the pulse is apt to be slow. The pupils are at first contracted or unequal, later they are widely dilated.

The treatment is properly directed to the primary disease. For the cerebro-spinal symptoms the methods described above are to be tried, but the prognosis is very bad, such cases being almost invariably fatal.

III. *Acute External Meningitis, Acute Pachymeningitis, Acute Peripachymeningitis ("Periméningite Aiguë").*—By some authors these are considered two different affections, the latter involving the peridural connective tissue only, the former the dura itself.

"Perimeningitis" was first described and named by Albers in 1833 as a primary acute affection of the connective tissue surrounding the dura mater. He reported two cases. In 1879 Leyden proposed the name peripachymeningitis, a name which has been generally accepted by the Germans, while the French have adhered to the original name. The disease is a rare one. Deléarde in 1900 reviewed the literature and collected sixteen cases, adding one of his own. Of these, fourteen were men, the larger number being between the ages of twenty and thirty, the exciting cause apparently exposure and overexertion. Autopsy revealed the presence of inflammation in the peridural tissue only, which sometimes extended to the tissues around the vertebral column, but was essentially primary in the connective tissue surrounding the dura.

The port of entry for the infection is unknown. The organisms isolated are the staphylococcus aureus in two cases (Antony and Netter), the streptococcus in one (Deléarde). As the dura is free from the vertebral column laterally and posteriorly, the inflammatory exudate tends to collect on these surfaces and may travel out through the intervertebral foramina along the spinal nerves, as in Meslier's case. The effusion may be serous and abundant, or fibrinous, forming a false membrane over the outer surface of the dura; or, especially in the very rapid cases, it may consist of a small amount of bloody pus. The extent of the exudate varies much. Usually the cord is softened at the point of greatest inflammation, but is normal above and below.

There are no pathognomonic symptoms. The onset is usually sudden, with pain in the limbs and paraplegia, but without spasm and with normal or diminished reflexes. Anæsthesia appears early, preceded by lightning pains, and usually there is a zone of hyperæsthesia just above the anæsthetic area. Pressure on the spine over the inflamed region is very painful. The general symptoms are fever with morning remissions and a typhoid condition. Death is preceded by a fall of temperature (89.6°, F. in the rectum was noted in Lemoine and Lannon's case). Symptoms of internal meningitis, muscular spasm, rigidity of the neck, etc., appear late, if at all, and are evidences of an extension of the process to the pia-arachnoid. The rapid paralysis and anæsthesia without spasm or contraction are the chief diagnostic symptoms.

The prognosis is extremely bad. One case, that of Antony, operated on by Chipault, who performed laminectomy of the seventh to the eleventh dorsal vertebræ, recovered temporarily, but soon succumbed to suppurative endocarditis. Usually death occurs early. Meslier's case, lasting eight days, is the longest in Deléarde's series. Asphyxia from paralysis of the muscles of the thorax is the most common cause of death.

Pachymeningitis or peripachymeningitis secondary to some inflammatory process in the body is, according to the authors quoted above, to be strictly distinguished from the primary form, but the usual text-books make no such distinction, nor do they lay much stress on the limitation of the process to the dural or to the peridural tissue. Caries of the vertebræ is, naturally, the commonest cause of this condition; then follow suppurative processes near the vertebral canal, as psoas abscess, abscess of the muscles of the back, retropharyngeal abscess, deep sacral bedsores. Gowers believes that most of these cases of so-called secondary pachymeningitis are in reality cases of primary meningitis with secondary abscess formation. The inflammation almost never passes through the dura to the pia-arachnoid. Usually the inflammatory exudate is semipurulent and forms a layer over the outer surface of the dura, especially in the space between the posterior surface of this membrane and the arches of the vertebræ. In those cases which follow caries of the spine the vertical extent of the process is limited to the extent of bone disease. In any case gravity seems to affect the distribution of the exudate, for it rarely rises above the upper cervical region. In acute cases the symptoms are similar to those of the primary form, but not so rapid in development, and they are apt to be somewhat masked by the accompanying disease. Bedsores develop rapidly if the disease lasts long enough.

The only form which affords opportunity for treatment is that in which there is an accessible focus of inflammation which can be treated surgically. Trephining and free drainage of the vertebral canal is indicated. The general treatment follows that outlined for cerebro-spinal fever.

IV. *Tuberculous Meningitis.*—This form properly occupies a place between acute and chronic meningitis, for it may be acute, subacute, or chronic. It is divided by some authors into primary and secondary, but the primary cases rest on a very infirm base. Councilman has never seen a primary case, and Osler considers such cases very doubtful. A careful search will in almost all cases reveal an old tuberculous focus, if not in the lungs then in lymphatic glands, bone, or even in the middle ear. Jacobäus attributed a case of tuberculous meningitis of the cauda equina to extension from a tuberculous endometritis.

The process is more marked in the cerebral than in the spinal membranes, and the symptoms of spinal meningitis may be masked entirely, yet it is probable that in all cases the spinal meninges are also involved. Lichtheim found tubercle bacilli in the fluid obtained by lumbar puncture in all the cases of tuberculous meningitis examined in his clinic (figures not given); Fürbringer in twenty-seven out of thirty-seven cases. Oppenheim, Heubner, and Leyden and Goldscheider consider extension to the spinal meninges almost invariable. Osler reports a case of pure spinal meningitis (tuberculous). The localization of the process in the membranes at the base of the brain has led to the name "basilar meningitis," the large amount of fluid exudate to the name "acute hydrocephalus" or "water on the brain." It is much more common in children than in adults, but is rare during the first year of life; more common from the second to the fifth years.

The membranes at the base of the brain are cloudy, and covered with an exudate which is serous or gelatinous, or semipurulent, and causes matting of the membranes. There may be numerous tiny white tubercles scattered throughout, or they may be very few and revealed only after a careful search. They tend to form along the small pial arteries, and examination of the choroid plexus may reveal them, or it may be necessary to make a careful dissection of the branches of the middle cerebral arteries, when they will be found along the sheaths of the smaller vessels. Though more fully developed in the basilar region, the tuberculous process spreads to the vertex and to the vertebral canal. The abundant exudate—which is no measure of the extent of the tuberculous process—may cause flattening of the convolutions of the brain and enormous distention of the ventricles. Lichtheim says that the fluid is generally clear, but a delicate veil of fibrin often appears on standing, and is apt to contain in its meshes tubercle bacilli.

The tubercles are miliary, but have a tendency to early caseation, which is found even in the rapid cases—those of nine or ten days. In the slower cases there is an extensive confluence of the tubercles with formation of large caseous masses, in which the bacilli are found in great numbers. Giant cells are not common. Hektoen has described a peculiar tuberculous endarteritis which is not an extension from without, but due to an implantation of bacilli from the blood. The dura may escape entirely, or may show simply congestion. Ophüls describes tubercles of the ependyma either deep, from infection through the lymphatics, or superficial, from infection through the cerebro-spinal fluid.

The prodromal stage is protracted as compared with that of purulent meningitis, and the disease follows well-marked stages. The symptoms of the prodromal stage are headache, listlessness, irritability, constipation, loss of appetite, more or less insomnia. These may pass gradually or suddenly into the stage of irritation: severe headache, vomiting, fever, often convulsions. Headache is apt to be intense and agonizing, requiring powerful sedatives and being sometimes uncontrollable. The temperature rises rather gradually and is not high, 100–103 F., the pulse increasingly irregular. In this stage the pupils are contracted, and there are muscular twitchings or spasms. The next stage is marked by a subsidence of the irritative symptoms, the headache is less severe, the head retracted, the patient is dull and stupid, the eyes half closed, the eyeballs moving slowly from side to side, or there may be strabismus, the pupils dilated. Sudden flushes may appear over limited areas and redness follows rubbing or passing the nail quickly over the skin (the tache cérébrale). Convulsions may occur in this stage, which passes over into the stage of paralysis, characterized by a low delirium or coma, with dilated pupils, a weak, rapid pulse, a subnormal temperature, and sometimes paralysis of face or limbs. Death occurs in two to three weeks, sometimes preceded by a sudden rise of temperature.

The type described is that usually seen in childhood. In adults the process is extremely variable. Chantemesse, Boix, and Jaccoud all emphasize the great difference between the form in childhood and that in adult life, Jaccoud, indeed, asserting that the fatal outcome is the only common symptom. Jacobäus, however, explains this partly on the ground that it is the unusual cases only which find their way into the literature. The onset may be very sudden and the disease fatal within a few days. A case of Heubner's—adult—was at work up to thirty hours before death. He was seized with convulsions, delirium, and finally lethal coma. In other cases the disease may apparently begin in the spinal membranes and affect the cerebral secondarily. In a case of Jacobäus', a pulmonary consumptive, the symptoms began in the legs and travelled up. Boix reports a case which simulated tetanus, being ushered in by trismus.

The diagnosis of tuberculous meningitis depends upon the discovery of a tuberculous focus elsewhere in the body, the long prodromal stage, the comparatively low temperature, the marked irregularity and slowness of the pulse, and the more gradual development of the distinctive symptoms of meningitis than occurs in the purulent form. Ophthalmoscopic examination may reveal tubercles of the choroid. The value of Quincke's lumbar puncture has already been emphasized.

The disease is almost invariably fatal. Von Leube reports one recovery. A young phthisical adult had symptoms of tuberculous meningitis, recovered, suffered an exacerbation of the symptoms in the lungs, and succumbed to a second acute attack of meningitis. Examination of the spinal membranes showed evidence of healing tubercles. Reinhold had a case which followed a similar course. In the fluid obtained from a case of supposed epidemic meningitis Freyhan found tubercle bacilli, but the patient recovered. Osler has never seen a case diagnosed as tuberculous recover, nor has he found evidence of past disease at autopsy. *Alice Hamilton.*

SPINAL-CORD DISEASES: CERVICAL HYPERTROPHIC PACHYMENINGITIS.—The first adequate description of this rare disease was given by Charcot in a communication to the Société de Biologie in 1871. Two years later it was made the subject of a thesis by Joffroy, and since that time all writers on nervous diseases have associated the names of these two observers with classical descriptions of this form of meningitis.

Pathologically the disease is characterized by a chronic inflammation beginning on the inner aspect of the dura, and resulting in an exuberant stratiform overgrowth of fibrous tissue. As a result the dura may attain to a thickness five to ten times greater than the normal. The spinal roots traversing the thickened meninges are at first irritated and finally more or less completely strangled by the fibrous overgrowth. Later on, the cord itself shares in the morbid process, either by mechanical compression or by actual invasion, in the latter case the inflammation creeping in along the pial septa and blood-vessels. The ultimate result is a welding together of membranes, roots, and cord in a dense, stratified mass of fibrous tissue which may undergo partial ossification. Vacuolation of the cord has been said to occur as an end result in certain cases, and is probably due to the retraction of the fibrous tissue.

The disease usually begins in the dura surrounding the lower portion of the cervical cord, and produces a fairly constant clinical expression of its presence; it may, however, invade the pons and medulla or involve the upper dorsal region.

From an etiological standpoint nothing definite is known about the disease. Charcot speaks of it as accidental, having nothing to do with the family or hereditary types of nervous affections. Exposure to cold and damp seems to be the chief causative factor, although traumatism is accorded its usual place in the list, probably for the sake of uniformity. Oppenheim thinks that syphilis is a very common if not a prime cause; in the opinion of the writer the disease is much too rare to warrant this view.

The symptomatology has been somewhat arbitrarily divided by Charcot into three periods corresponding to the three stages of pathologic development. In the first—neuralgic or pseudo-neuralgic period—there is very severe pain in the neck, in the back of the head and between the shoulders, and sometimes in the top of the chest. With this there is a feeling of tension or stiffness, and the cervical spine may be tender to percussion. In addition, paræsthesiæ and neuralgic pains appear in the regions supplied by the ulnar and median nerves—the radial practically escapes—and are accompanied or followed by tremor and a certain degree of muscular tension. This stage of the disease may last for from four to six months, and is usually followed by the second or paralytic period.

At the beginning of this second period the pain has practically subsided. Paralysis of neuritic origin has, however, succeeded. This paralysis corresponds chiefly to the distribution of the ulnar and median nerves, the radial practically escaping. The muscles mainly involved are the small muscles of the hand and the flexors of the hand and fingers. As a result the unantagonized action of the extensor group brings about a peculiar attitude of the hands—hyperextension at the wrist-joint, with extension of the basal and flexion of the middle and end phalanges. This is known as the preacher hand (*main de prédicateur; Prediger hand*) and is practically pathognomonic. The reason for the exemption of the radial nerve from participation in the morbid process is not obvious, since its roots certainly lie within the diseased dural territory. It is curious also that mention is not oftener made of an implication of the cilio-spinal fibres of Klumpke-Dejerine arising from the first dorsal segment of the cord, with consequent changes in the pupil and in the palpebral fissure.

The third symptomatologic period is not always clearly to be separated from the others. In it appear the signs of a break in the conductivity of the cord, the result of strangulation or infiltration. This is evidenced by spastic paraplegia, anæsthesia, and loss of control of the vesical and rectal sphincters. These symptoms are produced in part by the local compression or asphyxiation of the cord, as has been stated, and in part by the secondary degenerations which naturally result therefrom.

As a rule, the disease extends over a period of years. It may, however, come to a standstill at any stage, leaving permanent damage which corresponds in degree with the amount of cord or nerve destruction that has taken place, or allowing complete restitution to the normal. Fatal cases are recorded.

When the disease process occurs in the classical situation, the lower portion of the cervical enlargement, its clinical features are sufficiently characteristic to determine the diagnosis. Obscurity comes when there is bulbar or pontine involvement or when the upper dorsal cord and roots are mainly implicated. An early cervical Pott's disease may be mistaken for cervical hypertrophic pachymeningitis; in such a case the obvious implication of the vertebræ themselves, which occurs sooner or later in the course of Pott's disease, should serve to differentiate. From tumors starting in the meninges or from the cord itself and growing vertically, differentiation is very difficult if not impossible; here the rarity of the disease under consideration should influence the decision.

The therapeutic measures most indicated are hot baths, the local application of the actual cautery over the lower cervical vertebræ, and the internal administration of potassium iodide and mercury, the last two being of value even in cases which are not specific in origin. In a case of Remak's galvanism rendered good service. Surgical measures are to be avoided. *Joseph W. Courtney.*

SPINAL-CORD DISEASES: CHRONIC SPINAL MENINGITIS.—Localized areas of chronic meningitis accompany chronic disease of the bones of the spinal column, tumors, chronic inflammatory diseases of the cord, etc. It is practically impossible to separate chronic pachymeningitis from chronic leptomeningitis. The process may predominate in one membrane and the symptoms may vary accordingly, but the other is invariably involved to a greater or less extent. Chronic productive inflammation of the pia-arachnoid and dura mater is very common, especially in old age; it is associated with trauma, atrophy of the cord and brain, chronic alcoholism, and general paralysis. It is usually accompanied by hemorrhage into the newly formed tissue and is therefore denominated pachymeningitis interna hæmorrhagica. In the early stages the inner surface of the dura mater is covered with a fine, easily removable, veil-like membrane consisting of a fibrinous network with spindle-shaped connective-tissue cells and leucocytes. Gradual organization of this membrane takes place by the formation of connective-tissue fibres, and the outgrowth of vascular buds which form a rich vascular network. These thin-walled vessels are very prone to rupture, so that the membrane becomes studded, at first with hemorrhages, later with masses of blood pigment from the disintegrated corpuscles. The outer part, next the dura, grows sclerotic, and is inseparable from the dura itself. Large hemorrhages may occur—hæmatoma of the dura—with symptoms of compression. The early stages may be found at autopsy, in acute infectious diseases, without having caused symptoms during life.

Undoubtedly many cases of so-called "chronic meningitis," especially those of the earlier literature, were really diseases of the cord, for chronic spinal meningitis is rare as a primary malady, and our knowledge of it is as yet slight and defective. The clinical picture differs widely from that of the acute, for the symptoms of irritation are replaced by those of pressure. The nerve roots seldom escape in this form. Usually they are red and swollen or compressed and atrophied. The cord suffers to a variable degree, most extensively where the process is pronounced in the pia-arachnoid, and the newly formed tissue not only compresses the nerve roots, but passes in along the sheaths of the vessels, causing a marginal sclerosis and a general infiltration of round cells and epithelioid cells. Degenerations following this sclerosis cause the symptoms of a mixed lesion, a meningomyelitis. Usually the changes are localized, especially in the cervical cord; very rarely they are general, as in a case reported by Mitchell Clarke, in which the pathological changes and new formation of connective tissue rich in blood vessels involved the inner surface of the dura and the pia-arachnoid throughout the whole extent of the cord.

The symptoms of chronic meningitis are due, as in the acute form, to irritation and compression, but in the former there are not such severe paroxysms or spasms, and the symptoms increase gradually, at times with long remissions. Pain or stiffness in the back and neck, with radiating pains in the limbs, simulate rheumatism. This is succeeded after a long period by anæsthesia, with hyperæsthetic patches. The muscular symptoms are tremors, gradual loss of power, and wasting. The reflexes are lost. The symptoms vary naturally with the localization of the lesions. Those of the cervical cord are muscular atrophy and paresis of the upper extremities with spastic laming of the lower, and are very similar to those of amyotrophic lateral sclerosis or syringomyelia, except for the more pronounced pain and stiffness.

The form known as pachymeningitis cervicalis hypertrophica was first differentiated by Charcot and Joffroy, who claimed for it a special symptomatology. The thickening of the dura is most pronounced in the cervical cord, where it forms a ring of dense fibrous tissue, with adhesions to the bony canal and to the pia-arachnoid. The outgoing nerve roots are compressed and show degeneration with proliferation of interstitial tissue. Pressure on the periphery of the cord causes a marginal sclerosis which is followed by ascending and descending degenerations. The proliferation of new tissue may be so extensive as to flatten the cord antero-posteriorly.

Charcot divides the symptoms into a first period lasting two or three months, with severe pains in the back of the neck passing up to the occiput and down to the arms, persistent, with exacerbations. There are rigidity of the neck and back, simulating Pott's disease, paræsthesia in the arms, perhaps paresis. This corresponds to the stage of compression of the nerve roots, while in the second stage there are the symptoms of degeneration, the pains cease, there are laming and atrophy, especially of the muscles supplied by the ulnar and median nerves. There are laming and contraction of the muscles of the legs, also general cutaneous anæsthesia, decubitus, and there may be paralysis of the sphincters.

The prognosis is grave, for the disease is usually regularly progressive, and a recovery probably speaks for a wrong diagnosis. Rest is essential; warm baths and counter-irritation, by stimulating liniments or sinapisms, may be employed. Joffroy recommends the use of the thermo-cautery for the hypertrophic form. Mercury and iodide of potassium are recommended, the former by inunction over the spine, and combined with cantharides for counter-irritation. In using anodynes it is important to bear in mind the long course of the disease and the importance of frequently changing the drug and of trying to reduce the dose occasionally. Galvanism, massage, and passive movements are indicated for the muscular wasting.

Syphilitic Meningitis.—It is very probable that many of the cases which are diagnosed as chronic meningitis are syphilitic in origin. The most common change found in the spinal cord in syphilis is meningomyelitis, which generally affects the membranes of the brain as well. Williamson states that in thirty-two cases of spinal syphilis examined by him, sixteen were meningomyelitis, three were chronic meningitis. The syphilitic process shows itself in the vessel walls especially, although the weight of opinion is against a specific syphilitic arteritis. A general arteritis, however, in young individuals is apt to be syphilitic. The dura is diffusely infiltrated and thickened, there may be typical gummata with caseous centres, but more frequently there are only local accumulations of new connective tissue. The pia may in some places exhibit five to ten times its normal thickness, being gelatinous or densely fibrous, and adherent to the dura. The changes in the membranes extend to the cord in the form of proliferation of the connective tissue along the sheaths of the vessels and of the neuroglia. The changes in the vessels are proliferation, sometimes most marked in the intima, sometimes in the adventitia, with thrombosis and obliteration of the smaller vessels. Japha, Schwarz, and Wullenweber report cases of syphilitic meningitis accompanied by cavity-formation in the cord, the cavities being caused probably by necrosis of anæmic infarcts from the blocking of the sclerotic vessels. This condition is not to be confused with syringomyelia, for there is no trace of gliosis around the cavities.

Chronic syphilitic meningitis can cause any of the symptoms outlined under chronic meningitis in general, depending on the localization of the fibrous proliferation. Typically, it is focal in character and associated with focal lesions in the cord itself, so that the pains are usually irregular, unsymmetrical, followed soon by impairment of sensibility and muscular weakness. The pain is said to be worse at night. The rise of temperature is not great—100°–101° F.—and may be subnormal at the end. In Shoyer's case the symptoms began in the left foot and moved gradually upward, the disease lasting over four years.

The prognosis is more favorable than that of any other form of chronic meningitis; the treatment follows the same lines as that for syphilis in general.

Alice Hamilton.

SPINAL-CORD DISEASES: COMBINED DEGENERATIONS OF THE CORD.—INTRODUCTION.—The attitude toward the so-called combined scleroses of the spinal cord has changed with increasing post-mortem study and with the general acceptance of the neurone doctrine as applied to pathological processes. The term "system or systemic disease," as formerly applied by Charcot and others, should be modified to include only degenerations of neurones, "systemic neurone disease," whereas the various degenerations, involving chiefly the white matter of the cord, irrespective of neurones, should be differently classified. A failure to recognize this fact, even on the part of recent writers, has led to a very considerable degree of confusion in the nomenclature, especially since lesions of varying extent and character may give rise to very similar clinical symptoms. With the more accurate study which the new conception of the anatomy of the nerve cell has rendered possible, and with a large number of post-mortem investigations, it is apparent that the "combined scleroses" are more frequently diffuse in distribution than limited to fibre tracts of functional identity. If, then, the term "combined sclerosis," or "combined disease of the dorsal and lateral tracts," be used, it should be understood that there is no implication that the neurones as such are primarily involved, although the lesions may lie, in great part, in the lateral and dorsal portions of the cord. Doubt has been thrown upon the existence of a true systemic degeneration of the peripheral sensory neurones (dorsal tracts), and the central motor neurones (pyramidal tracts) in the form of a combined disease (Goldscheider), except in certain hereditary affections (Friedreich's ataxia, cerebellar ataxia) and in dementia paralytica. It is certainly far less frequent than formerly believed. In the following discussion, therefore, I shall place chief stress upon diffuse lesions of the cord, predominantly located in the dorsal and lateral tracts, and giving rise to the symptoms of ataxic paraplegia. This in no way denies the possibility of the existence of combined disease which is actually systemic in character.

The following provisional groups may be made:

I. Diffuse (combined) degeneration of the cord; combined sclerosis.

II. True combined dorsal and lateral systemic (neurone) disease.

III. Combined systemic disease. (*a*) Result of congenital defect (Friedreich's ataxia, cerebellar ataxia). (*b*) In dementia paralytica.

I. *Diffuse (Combined) Degeneration of the Cord; Combined Sclerosis; Subacute Spinal Ataxia; Subacute Combined Degeneration of the Spinal Cord; Combined System Disease.*—Under these varied titles has been included a type of affection which is sufficiently characteristic to have a definite place among the diseases of the spinal cord. Attention has been drawn to the combination of sclerosis of the dorsal and lateral tracts by Kahler and Pick, Westphal, Strümpell, and Oppenheim; the association of such alterations with pernicious anæmia and cachectic states has become familiar through the work of Lichtheim, Putnam, Dana, Minnich, Nonne, Burr, Bastianelli, Russell, Batten, Collier, very recently by Billings, and many others. The identity of the lesions in these various conditions is still in dispute; that they vary in detail is of course natural and inevitable; that they represent a general group of alterations which may later be subdivided is, however, at present a supposition, justified by the facts at our disposal. No attempt at subdivision—as, for example, lesions due to anæmia or lesions dependent upon general cachexia or toxæmia—will be attempted in what follows. Anæmia has undoubtedly been given a place of undue importance in relation to these lesions. The insistence upon other and more general causes is due primarily to Putnam's work, published in 1891.

PATHOLOGICAL ANATOMY.—The alterations in the cord in this type of disease consist macroscopically in degenerations of the white matter, chiefly in the dorsal and lateral tracts, irregular in distribution, and either not involving whole groups of fibres or extending beyond the confines of such tracts. The dorsal tracts, for example, are affected irregularly, groups of fibres in the immediate neighborhood of much degenerated areas are spared, and the root zones are rarely involved, in striking contrast to the systemic degeneration of tabes. The region of the pyramidal tracts is often much involved, but the alterations always extend beyond the confines of these tracts, chiefly along the peripheral portions of the cord, and on either side of the ventral fissure. The alterations are least marked in the lumbar region, and increase markedly in extent in the upper thoracic and cervical regions. Even to the naked eye the stained section often presents a peculiar, vacuolated appearance. Microscopic examination of the lesions shows the alterations to be essentially limited to the cord, with exceedingly slight alterations of the oblongata or hemispheres. The lesions are characterized by disintegration of myelinated fibres, overgrowth of neuroglia, in part sufficient to form a dense sclerosis and in part slight, vacuolation being due apparently to dilating and degenerating myeline sheaths, many fat granule cells, irregularity of distribution, often with very small foci of degeneration, scattered irregularly through the white matter, and at times focal softening. The gray matter is very slightly involved, and frequently not at all; the nerve roots are not involved; there is no evidence of meningeal thickening, and the blood-vessel walls rarely show changes. The pathological features common to the general group may, therefore, be summarized as follows:

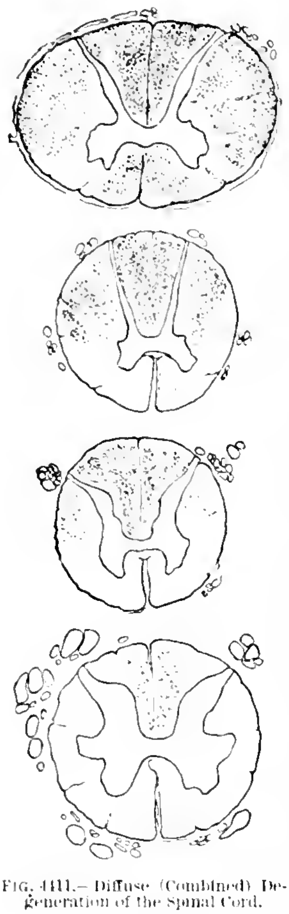

FIG. 4411.—Diffuse (Combined) Degeneration of the Spinal Cord.

1. A diffuse degeneration for the most part limited to the cord, often in more or less discrete patches.
2. A constant involvement of the dorsal and lateral columns, without strict regard to neurone systems.
3. A predominance of the lesion in the cervical and thoracic regions.
4. The common freedom from degeneration of nerve roots, both motor and sensory, and peripheral nerves.
5. The essential non-involvement of gray matter.
6. Insignificant vessel changes.

The reason for the peculiarly constant location of the lesions is probably to be sought in the distribution of the blood supply to the cord, a theory first advanced by Marie. Those who cling to the systemic character of the affection are inclined to search for a more subtle explanation, but the involvement of the cord alone, the tendency toward a peripheral distribution of the lesions, the non-involvement of gray matter, and the frequent occurrence of the disease in impoverished blood states, all indicate the rôle of the blood-vessels and their contained blood. Certain writers have maintained a double lesion, one of diffuse character and the other systemic, with possible secondary degenerations.

ETIOLOGY.—The persons in whom the disease occurs in typical form are usually of middle age, weak constitution, often with neurotic personal or family antecedents, of poor nutrition, cachectic in appearance, and of reduced bodily vigor. It is considerably more frequent in women than in men, according to Putnam's statistics. Syphilis may be disregarded as an etiological factor. A frequent though by no means universal accompaniment or possible cause of the disease is anæmia of the pernicious type. This association has led to the popular but wholly erroneous assumption that the alterations of the spinal cord described above are peculiar to anæmia. Lead poisoning, malaria, grave secondary anæmia, and other debilitating influences have also been given as causes, and the disease has at times occurred in otherwise healthy individuals. Overwork, excessive anxiety, gastro-intestinal disorders, may have a predisposing influence. Further than this our accurate knowledge does not go. Whether or not a subtle toxæmia, of a character as yet not understood, may ultimately be found responsible is possible, but far from being proved. It may be said with assurance at the present time that a well-characterized affection of the cord occurs in cachectic individuals toward middle life, leading to diffuse, quasi-systemic degenerations, dependent, in part at least, upon the distribution of the vascular supply.

SYMPTOMATOLOGY.—In general, during the early stages, the symptoms are somewhat vague in character and may simulate functional disorders. The most conspicuous early symptom is paræsthesia of the extremities, noticed earlier in the feet. Disordered sensations may occur in other portions of the body—genitals, distributions of cranial nerves—but are much less usual. This paræsthesia is frequently very distressing. Slight disorders of micturition and rarely of defecation may occur. Objective disorders of sensation are not conspicuous, though they certainly occur, and in a well-reported group of cases (Russell, Batten, Collier) take an important place in the later stages of the clinical picture. Disorders of motion are of the character of a slight spastic paraplegia, with exaggerated deep reflexes, and the Babinski phenomenon. As the disease progresses, the symptom-complex assumes the general character of an ataxic paraplegia, with a predominance of ataxia or paraplegia depending upon the greater involvement of the dorsal or lateral columns. In later stages, as the lumbar portion of the cord is invaded, the knee-jerk may be abolished, and the patient be reduced to a helpless paraplegic condition, with loss of sphincter control. The mind is rarely affected, and the cranial nerves show no noteworthy involvement. Pigmentation of the skin, epileptic attacks, excessive diarrhœa or constipation, atrophy of the optic nerve, mental instability, dissociation of sensation, pain in the back and limbs, transient œdema, muscular atrophy, altered electrical reactions, have all been described as occasional symptoms.

Certain writers, notably Bastianelli and Russell, Batten and Collier, have attempted to classify cases either by etiology (Bastianelli) or by symptomatic course (Russell, etc.). The latter divide the disease sharply into three stages: first, slight ataxic paraplegia, constituting one-half to three-quarters of the duration of the illness; second, sudden loss of sensation, with increasing motor paresis, leading to inability to walk or stand, marked spastic paraplegia; third, stage of flaccidity, flaccid paraplegia, complete flaccid motor paralysis, complete anæsthesia, with loss of deep reflexes, incontinence, wasting of muscles, and loss of faradic reaction. In the experience of others these sharp divisions cannot be maintained; such a course evidently marks a variety of the general affection, which is highly important, but cannot be regarded as characteristic of the entire group. In general, it must be said that on the symptomatic side attempts to deduce a perfectly characteristic clinical picture have as yet failed, although the grouping of the symptoms of primary paræsthesia, ataxic paraplegia increasing rather rapidly in intensity, followed by a stage of more or less complete motor and sensory paralysis, in the absence of lancinating pains and Argyll-Robertson pupil, point strongly toward combined lesions of the character under consideration.

Diagnosis, Course, and Prognosis.—The diagnosis in the later stages should not be difficult, and in the early stages should be assumed as probable in cases in which an otherwise unexplained and persistent paræsthesia, especially of the legs, is associated with slight ataxia and a tendency toward spasticity with exaggerated deep reflexes, particularly if the patient be of middle age, with evidences of cachexia. Multiple sclerosis may simulate this affection at various stages, but in general it may be distinguished by the youth of its victims, the characteristic speech defect and tremor, with a marked preponderance of motor over sensory involvements. Myelitis should also receive consideration in the differential diagnosis. Uncomplicated tabes should give rise to no confusion.

The course of the disease is from six months to two years, with occasional instances of much longer duration. As a rule, the patients are already in a debilitated condition when the symptoms manifest themselves, a fact which evidently must have a more or less direct bearing upon the outcome.

The prognosis is always bad, both from the point of view of the general condition of the patient and also because of the usually rapidly advancing cord degenerations.

Treatment.—Attention should first be directed toward the discovery and amelioration of the underlying condition causative of or associated with the alterations in the cord. Anæmia, whether of the so-called pernicious variety or secondary, general debility, and disordered bodily functions in general, should be treated by the recognized means at our disposal. It is possible that much might be done in the earliest stages to avoid or modify the serious and ultimately irremediable cord degenerations. If they have developed, however, and the patient is ataxic, or ataxic paraplegic, recourse should certainly be had to the Frenkel exercises, modified to meet the indications in individual cases. The usual drugs—iron, strychnine, arsenic, the iodides, etc.—may be given, but with small hope of permanent benefit.

II. *Combined Dorsal and Lateral Systemic (Neurone) Disease.*—In spite of the doubt which has been thrown upon the existence of a true neurone degeneration involving dorsal and lateral tracts, cases have been reported clinically, and in a few instances anatomically verified, of the existence of such a combined lesion (Oppenheim). Degenerations of the columns of Goll and Burdach, the pyramidal tract, the direct cerebellar tract, and less frequently of Gowers, and the uncrossed pyramidal tracts, have been described, with the assumption that these tracts were degenerated as systems and not as a part of a more general process.

Such cases of primary degeneration of lateral and dorsal neurone systems give rise to the symptoms of tabes and lateral sclerosis, the one or other type of symptom predominating in direct relation to the extent of the dorsal or lateral pathological change. Symptoms of tabes, with lancinating pains and Argyll-Robertson pupil, but with exaggerated knee-jerk, should always give rise to a strong suspicion of a combined systemic degeneration, giving the general clinical picture of ataxic paraplegia. Should the definite signs of tabes, including loss of knee-jerk, be associated with muscular weakness, a similar diagnosis of combined lesion is justified. The signs of tabes, on the other hand, may be in great measure subordinated to those of lateral degeneration—spastic paraplegia. In this case slight disorders of sensation, sharp pains, condition of the pupils, bladder weakness, should be carefully investigated to determine the possible involvement of sensory neurones. Ataxic paraplegia, as commonly observed, is no doubt usually due to the more diffuse process described above. The important differential point is the existence of a true tabes, which does not occur in the diffuse combined lesions.

The treatment is as indicated for the foregoing disease, and for Friedreich's ataxia.

III. *Combined Systemic Disease.—(a) Result of congenital defect (Friedreich's ataxia); cerebellar ataxia; hereditary cerebellar ataxia; (b) in dementia paralytica.*

(*a*) *Friedreich's Ataxia.*—See article on this subject.

Cerebellar Ataxia.—Hereditary cerebellar ataxia, type Nonne-Marie, bears a close resemblance to Friedreich's ataxia, except for the facts that the knee-jerks are increased, the pupils are immobile, there is atrophy of the optic nerve, there are marked disorders of sensibility, and club-foot and kyphosis do not develop. Lesions of the cerebellum and other portions of the brain have been found, and in one case (Menzel) a combined system disease of the cord.

(*b*) *Combined Systemic Disease in Dementia Paralytica.*—Alterations of the spinal cord (Westphal), in the form of degeneration of the pyramidal tracts or of the dorsal, sensory tracts, or of both, are frequent in dementia paralytica. Whether the alterations in the pyramidal tracts are to be regarded as primary neurone degenerations or as secondary to changes in the cortex remains in doubt.

Gowers' Ataxic Paraplegia.—In 1886 Gowers drew attention to a condition presenting the symptoms of degeneration in the dorsal and lateral tracts, to which the clinical name ataxic paraplegia was given. The classification of this condition is difficult, but from the description of the pathological alterations it should rather be included among the diffuse combined degenerations than among the true systemic diseases. After what has been said it does not require separate description.

SPINAL-CORD DISEASES: CONGESTION OF THE CORD.—Our actual knowledge regarding spinal congestion is very limited, and hypothetical statements that it is the basis of many nervous symptoms are unwarranted. The diseases in which it is uniformly found after death are those in which the patient has died in convulsions complicated by asphyxia, or in the early stages of myelitis. The only positive evidence that a spinal congestion has existed during life is the discovery of distended capillaries, accompanied by small capillary hemorrhages. Without the latter the congestion found may have been a post-mortem occurrence, due to the position of the body on the back.

The *causes of active congestion* are excessive muscular exertion, violent sexual excesses, poisoning by strychnine, alcohol, and carbonic oxide, the sudden arrest of menstruation or the stoppage of hemorrhage from piles, and possibly exposure to cold. Traumatism of the vertebræ, especially general concussion of the spine, such as occurs in railway injuries, probably causes active spinal hyperæmia, in a few cases examined capillary hemorrhages having been found after death in the cord. It is probable that spinal congestion is usually localized in the lower half of the cord, though the entire organ may be affected. An active hyperæmia of the anterior cornua is the first occurrence in poliomyelitis anterior, and this is usually quite extensive, while the actual process of inflammatory degeneration is subsequently limited to a small area. The latter produces the permanent atrophic paralysis of infants; to the former must be ascribed the temporary paresis of the first stage of the disease, which is always more extensive than the permanent paralysis.

The causes of passive congestion are the same as those producing this effect in the brain or other organs (*q.v.*).

The *symptoms of spinal congestion* are a sensation of weight and fatigue in the legs and back, increased by any effort, so that continued exertion is impossible; pains, numbness, formication, and sensations of heat and cold, with increased susceptibility to changes of temperature and to pain and touch in the extremities; weakness, but not paralysis, in the entire muscular system, attended by an increase of reflex excitability; a diminution of sexual power, and a diminution of control over the bladder and rectum not sufficient to be termed incontinence. Any symptoms more serious than these, such as severe tearing pains in the back and general hyperæsthesia, or such as girdle sensations, incontinence, and actual paralysis, must be ascribed to congestion of the spinal meninges as well as of the cord, or to disturbances of a grave nutritive kind initial to an actual myelitis. These symptoms are always bilateral and usually more marked in the lower half of the body, although the arms may become involved. They usually come on suddenly after some known cause; but occasionally a chronic congestion is suspected, which lasts for months, and is attended by symptoms of neurasthenia.

The *diagnosis of spinal congestion* is an uncertain one. When symptoms such as those described appear, and do not go on to more serious conditions, but gradually pass off, and no adequate cause can be found, the diagnosis can be made. If, however, serious symptoms of myelitis ensue, it must be admitted that the disease was myelitis from the outset, and not a simple hyperæmia. A long duration of symptoms of spinal congestion points rather to the existence of capillary hemorrhages, attended by small foci of inflammatory degeneration, or to nutritive changes in the spinal cord.

The *prognosis* should always be reserved, in view of the uncertainty of diagnosis and the possibility of myelitis.

The *treatment* should consist of absolute rest in bed, in a prone position; the application of cool cloths, wet with an evaporating lotion, to the spine, or an ice bag or the ether spray; saline purgatives; and full doses of ergot with small doses of belladonna. *M. Allen Starr.*

SPINAL-CORD DISEASES: DIAGNOSIS OF LOCAL LESIONS IN THE CORD.—The spinal cord is a long, cylindrical organ, made up of numerous segments, each of which not only has a function of its own, but also bears an important part in relation to the functions of other segments. Each segment of the cord consists of a mass of gray matter, surrounded by a series of white tracts, from which passes out a pair of spinal nerves. In some of the lowest order of vertebrata the comparative independence of each segment is indicated by the fact that the spinal cord consists of a series of bulbous enlargements joined together by only a few connecting fibres. And even in man there are some evidences that the functions of each segment of the cord are independent of all others. But in the higher vertebrata the various segments are closely united to one another, and are also connected with the brain, which controls them all by means of the white tracts surrounding the gray matter. Hence, in addition to its own special function as a nervous centre, each segment has functions of transmission of impulses to adjacent segments and to distant parts of the nervous system. Therefore, in dealing with local lesions in the spinal cord, the first point to determine is whether the lesion involves the nerve centres of a single segment, or the tracts which pass through that segment to other centres. In the first case, when the gray matter of a single segment is affected, the symptoms are limited in extent and in number, consisting of localized paralysis, limited anæsthesia, loss of certain reflexes, disturbance of certain automatic actions, and local vaso-motor and trophic disturbances. In the second case, when the white matter of a single segment is affected, the symptoms are widespread and numerous, consisting of partial or complete paraplegia, anæsthesia of the lower half or even of the entire body, loss of control over reflex and automatic activity, and extensive vascular and trophic changes. And when both gray and white matter of a single segment are totally involved, there will be a combination of local and general symptoms, the distribution and extent of which will depend wholly upon the particular level of the segment of the cord which is affected. It is therefore evident that the first step in the diagnosis of local lesions of the spinal cord is the determination of the functions of the various segments, and of the various tracts which pass through them.

I. THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.—Each segment of the spinal cord consists of that portion of the entire organ which gives origin to one pair of spinal nerves. There are, therefore, thirty-one segments in the human cord. There is no natural division between adjacent segments, but if a cord with its nerves be carefully removed, there will be no difficulty in cutting it up into segments, each of which will receive two afferent and give off two efferent nerves. Each segment is made up of two symmetrical halves, naturally separated by the anterior fissure and posterior septum, but joined by a commissure.

The afferent or sensory nerves enter the posterior surface of the segment, and, passing through the white matter, end in the gray. The efferent or motor nerves pass out from the anterior surface of the segment, having their origin in the anterior gray horn, and traversing the white matter bordering these horns. The figure (Fig. 4412) shows four such segments at different levels of the cord with their afferent (*s*) and efferent (*m*) nerves as well as the motor tracts and association tracts to the various segments.

A. The Gray Matter.—The size and shape of the area of gray matter, seen in horizontal section of the cord, differ in almost every segment, the difference between adjacent segments being more marked in the cervical and lumbar enlargements than in the dorsal region. The shape of the area of gray matter in the dorsal region resembles that of the letter **H**, and, accordingly, anatomists describe two lateral halves with a central gray commissure between them, and in each half an anterior and a posterior horn. In the enlargements of the cord the mass of the horns is much larger than in the dorsal region, and the shape varies in each segment. The amount of gray matter in any segment depends upon the number of cells in the anterior and posterior horns. These cells are not scattered irregularly through the gray matter, but are collected into groups. These groups are quite distinct in the anterior horns, in some cases being small, and found only in a single segment; in others being long, and extending through several segments. This varying arrangement of the anterior groups at different levels is seen in the figure (Fig. 4413). The function of the cells in the anterior horn is to govern the motion and nutrition of the muscles.

The more exact localization of motor functions in the groups of cells in the cervical and lumbar enlargements has been attempted by various writers. Fig. 4413 shows the groups found at three different segments of the cord. There are some of these groups—viz., the inner antero-lateral and postero-lateral groups—which develop early in fœtal life, and are common to man and the less highly developed vertebrates. These are thought to govern the fundamental movements common to man and animals, and earliest acquired in children, viz., flexion and extension, abduction and adduction of the limbs. Other groups, viz., anterior and median groups, are found only in monkeys and man, and the central groups in man alone. These are also found to develop later than the others. They are therefore thought to govern the accessory movements, which are more specialized and depend on finer adjustment, such as the act of walking upright, pronation and supination, and the finer motions of the hands and fingers, actions which are learned some months later than those of a fundamental kind. In some cases of disease, limited to these groups of cells—*e.g.*, poliomyelitis anterior—the symptoms have been found to justify this distinction, loss of power and atrophy of certain muscles being produced by a lesion in certain groups of cells. The connection of the different groups, in various segments, with individual muscles, as far as at present known, is shown in the table accompanying this article.[1] (See p. 340.)

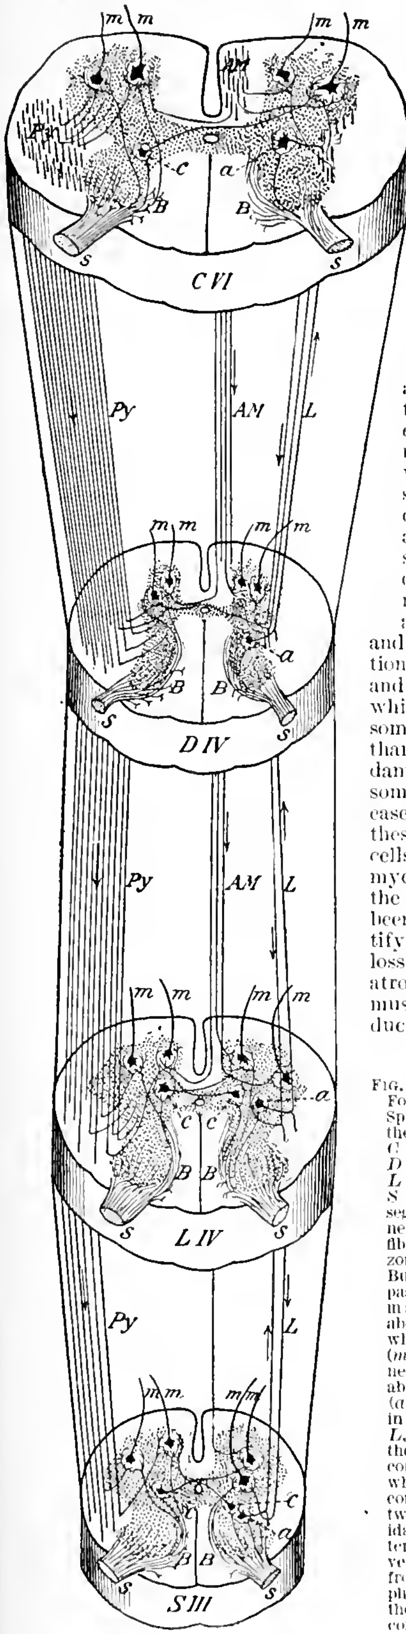

FIG. 4412.—Diagram of Four Segments of the Spinal Cord to Show the Motor Mechanism. *C VI*, Sixth cervical, *D IV*, fourth dorsal, *L IV*, fourth lumbar, *S III*, third sacral segments: *s*, sensory nerve root whose fibres enter the root zone of the column of Burdach, *B*, and then pass into the gray matter terminating about (1) motor cells whence motor fibres (*m*) issue as motor nerve roots; or, (2) about association cells (*a*) whose fibres pass in the lateral column *L*, to other levels of the cord, or (3) about commissural cells (*c*), whose fibres cross the cord associating the two sides. *Py*, Pyramidal tract; *AM*, antero-median tract conveying motor impulses from the right hemisphere of the brain to the motor cells of the cord.

The arrangement of cells in the posterior horns is different from that in the anterior horns. There is a column

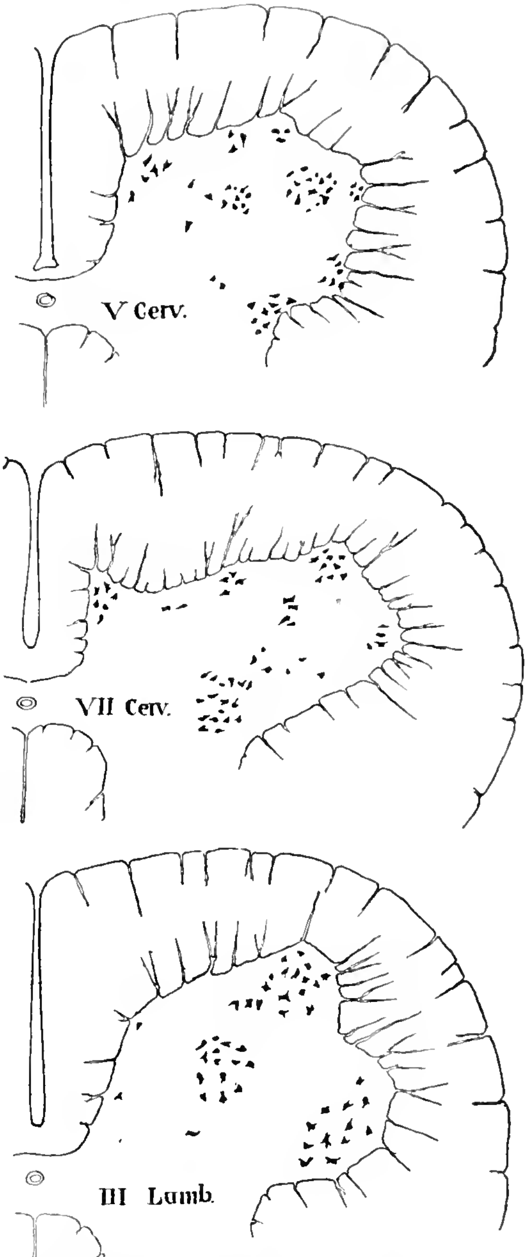

FIG. 4413.—Showing the Different Grouping of the Cells in the Gray Matter of the Spinal Cord at Three Different Levels. (Drawn from photographs.)

of cells extending through the lower dorsal region, known as the vesicular column of Clarke, and situated in the median and inner part of the horn (see Fig. 4412, *c*). The column begins in the third lumbar segment, and extends upward to the seventh dorsal segment. Its probable function is to regulate the vaso-motor and sympathetic nervous mechanisms.[2] There is a continuous column of cells in the middle of the posterior horn, not collected together into groups, but scattered through the neuroglia and gelatinous substance of the posterior horn. These cells are very small in size, and thus contrast markedly with those already described. It is probable that the gelatinous mass in the posterior horn has something to do with the sensory function, for it is present in the nervous system wherever a sensory nerve ends. The sensations of touch, temperature, and pain are carried into the posterior horns by the posterior nerve roots, which terminate in the gelatinous substance and in cells which lie about the central canal of the cord in the gray matter at the junction of the posterior and anterior horns (Fig. 4414, *X*).

All the cells of the gray matter give off branching processes which interlace, forming a dense network of nerve fibrillæ around the group of cells. This interlacing mass of fibres is composed partly of the dendrites of cells which collect impulses, and partly of the axones of cells which send out impulses. These axones in their pas-

LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.

Segment.	Muscles.	Reflex.	Sensation.
Second and third cervical.	Sterno-mastoid, trapezius. Scaleni and neck Diaphragm.	Hypochondrium (?) Sudden inspiration, produced by sudden pressure beneath the lower border of the ribs.	Back of head to vertex. Neck.
Fourth cervical......	Diaphragm. Deltoid. Biceps, coracobrachialis. Supinator longus. Rhomboid. Supra- and infraspinatus. Levator anguli scapulæ.	Pupil, fourth to seventh cervical. Dilatation of the pupil produced by irritation of neck.	Outer part of shoulder.
Fifth cervical...........	Deltoid. Biceps, coracobrachialis. Supinator longus. Supinator brevis. Deep muscles and shoulder blade. Rhomboid, teres minor. Pectoralis (clavicular part). Serratus magnus.	Scapular. Fifth cervical to first dorsal. Irritation of skin over the scapula produces contraction of the scapular muscles. Supinator longus. Tapping its tendon in wrist produces flexion of forearm.	Back of shoulder and arm. Outer side of arm and forearm.
Sixth cervical...........	Biceps, brachialis anticus. Pectoralis (clavicular part). Serratus magnus. Triceps. Extensors of wrist and fingers. Pronators.	Triceps. Fifth to sixth cervical. Tapping elbow tendon produces extension of forearm. Posterior wrist. Sixth to eighth cervical. Tapping tendons causes extension of hand.	Outer side of arm and forearm. Outer half of hand.
Seventh cervical.........	Triceps (long head). Extensors of wrist and fingers. Pronators of wrist. Flexors of wrist. Subscapular. Pectoralis (costal part). Latissimus dorsi. Teres major.	Anterior wrist. Seventh to eighth cervical. Tapping anterior tendon causes flexion of wrist. Palmar, seventh cervical to first dorsal. Stroking palm causes closure of fingers.	Front, back of arm and forearm. Middle and ring fingers.
Eighth cervical......	Flexors of wrist and fingers. Intrinsic muscles of hand.	....	Forearm and hand; ulnar area.
First dorsal............	Extensors of thumb. Intrinsic hand muscles. Thenar and hypothenar eminences.	....	Inner side of forearm.
Second and twelfth dorsal	Muscles of back and abdomen. Erectores spinæ.	Epigastric, fourth to seventh dorsal. Tickling mammary region causes retraction of the epigastrium. Abdominal, seventh to eleventh dorsal. Stroking side of abdomen causes retraction of belly.	Skin of chest and abdomen, in bands running around and downward, corresponding to spinal nerves.
First lumbar..........	Quadratus lumborum. Transversalis obliqui. Ilio-psoas. Sartorius.	Cremasteric, first to third lumbar. Stroking inner thigh causes retraction of scrotum.	Skin over groin and in front of scrotum.
Second lumbar.........	Ilio-psoas, sartorius. Flexors of knee (Remak). Quadriceps femoris.	Patella tendon. Striking tendon causes extension of leg.	Outer side of hip. Front of thigh.
Third lumbar.........	Quadriceps femoris. Inner rotators of thigh. Obturator. Adductors of thigh.	Bladder centre. Second to fourth lumbar.	Front of thigh. Inner side of leg.
Fourth lumbar	Abductors of thigh. Abductors of thigh. Flexors of knee (Ferrier).	Rectal centre. Fourth lumbar to second sacral. Gluteal. Fourth to fifth lumbar. Stroking buttock causes dimpling in fold of buttock.	Outer and back side of thigh and front of leg to ankle. Dorsum of foot.
Fifth lumbar......	Glutei. Biceps femoris. Semitendinosus. Popliteus. Outward rotators of thigh. Flexors of knee (Ferrier).	Achilles tendon. Over-extension causes rapid flexion of ankle, called ankle clonus. Babinski reflex. Scratching sole of foot causes extension of great toe. Fifth lumbar to first sacral.	Leg and foot, outer part.
First and second sacral...	Biceps femoris. Semimembranosus. Extensor longus digitorum. Gastric. Tibialis posticus. Tibialis anticus.	Plantar. Tickling sole of foot causes flexion of toes and retraction of leg.	Back of thigh and leg in saddle-shaped area. Inner side of foot.
Third sacral.......	Peronei. Intrinsic muscles of foot.	....	Back of buttock, seat.
Fourth and fifth sacral...	Sphincter ani et vesicæ. Perineal muscles.	....	Perineum, anus. Back of scrotum.

sage through the gray matter send off little fibrillary branches termed collaterals, which terminate in end-tassels about other cell bodies. Through this gray matter impulses pass in all directions, uniting the functions of the various cell groups, and of the sensory and motor areas of the cord. It is probable that impulses coming to the segment, either from the periphery or from the brain, are conveyed directly to the cells of the segment, and are distributed through the medium of the branches of the cells to several groups of cells.

Furthermore, each segment controls in some degree the processes of nutrition in the part of the body with which its sensory nerves are connected. It regulates the vasomotor tone in the organs and limbs, and it influences processes of growth and repair in the skin and mucous membranes. But the existence of trophic cells in the cord has not been proven. Nor can the automatic mechanisms of the cord be assigned to definite cells. They can only be referred to the gray matter of certain segments.

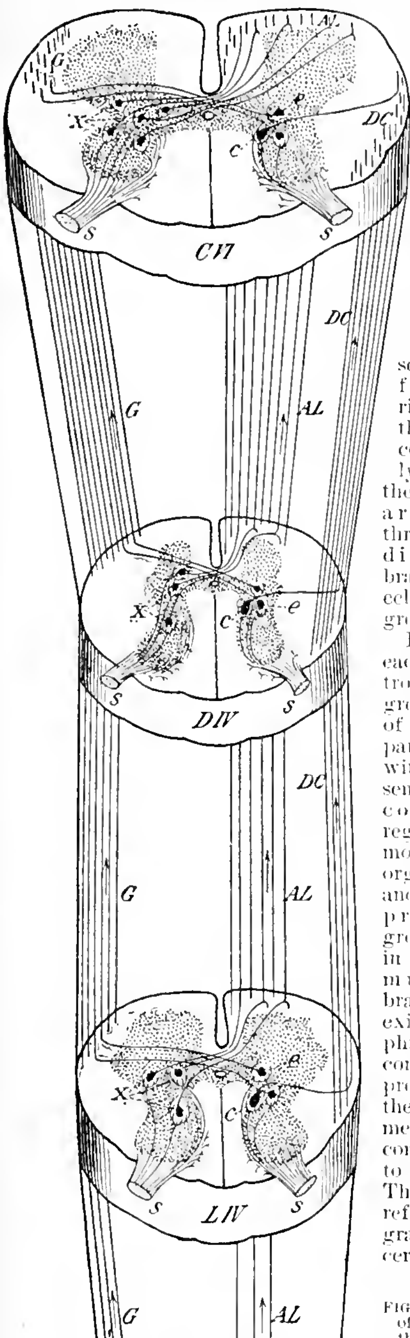

FIG. 4414. — Diagram of Four Segments of the Spinal Cord to Show Sensory Mechanism and Conduction. *S*, Sensory nerve root; *G*, column of Gowers; *AL*, antero-lateral column; *DC*, direct cerebellar column; *C*, cells of the column of Clarke sending fibres to *DC*; *X*, cells of the sensory gray matter sending fibres to *AL*; *e*, cells of the sensory gray matter sending fibres to *G*.

The function of the gray matter of the individual segments is shown in the preceding table. The facts upon which this table has been prepared are gathered from comparative anatomy, from physiological experiment, and from pathological observation. The level of the segment is given; the muscles governed by the groups of cells in it are mentioned so far as they are at present known; the reflex and automatic mechanisms governed by each segment are recorded, and the manner of producing the reflex acts; and the area of skin which sends its sensory nerves to the individual segments is described.

B. The White Tracts. — The gray matter of the spinal segment is surrounded by white nerve tracts, whose function is the transmission of impulses between adjacent and distant segments, and between the various segments and the brain. These tracts are quite numerous, and although in the normal adult cord they cannot be distinguished from one another, there are several means by which their lim-

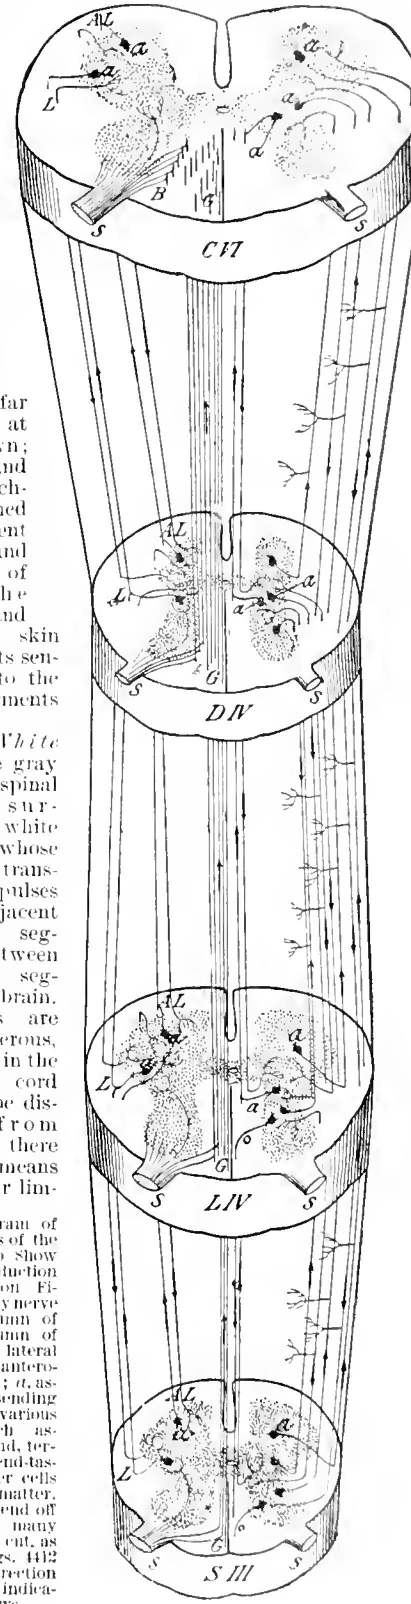

FIG. 4415. Diagram of Four Segments of the Spinal Cord to Show Sensory Conduction and Association Fibres. *S*, Sensory nerve root; *G*, column of Goll; *B*, column of Burdach; *L*, lateral column; *AL*, antero-lateral column; *a*, association cells sending axones into various columns which ascend or descend, terminating in end-tassels about other cells in the gray matter. These axones send off collaterals at many levels. In this cut, as well as in Figs. 4412 and 4414, the direction of impulses is indicated by the arrows.

its are determined. Thus in fœtal cords of various ages different tracts can be distinguished by the fact that they develop at different times. And in diseased cords pathological processes are often strictly confined to certain tracts. This is especially true of the processes known as secondary degenerations, by means of which the exact boundaries, the length, and the function of the various tracts have been ascertained. The older division of the columns of the cord into anterior, lateral, and posterior must be set aside in favor of the late divisions founded on these facts.

In a cross-section of the cord at the cervical region the following tracts are seen in each half of the segment:

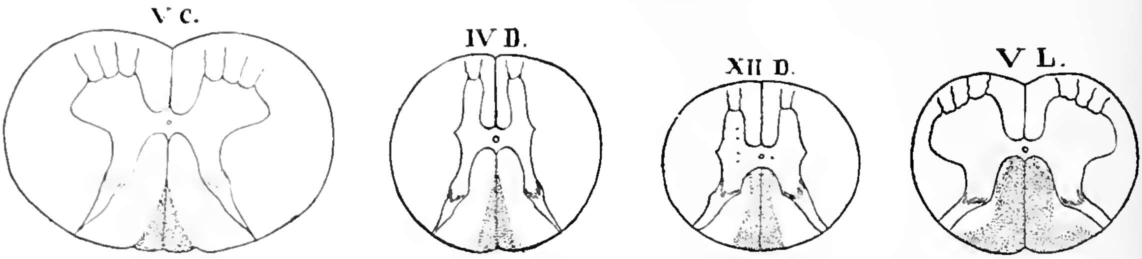

FIG. 4416.—Area of Ascending Degeneration in the Posterior Columns after Compression of Cauda Equina, Involving the Sciatic Nerve Roots only.

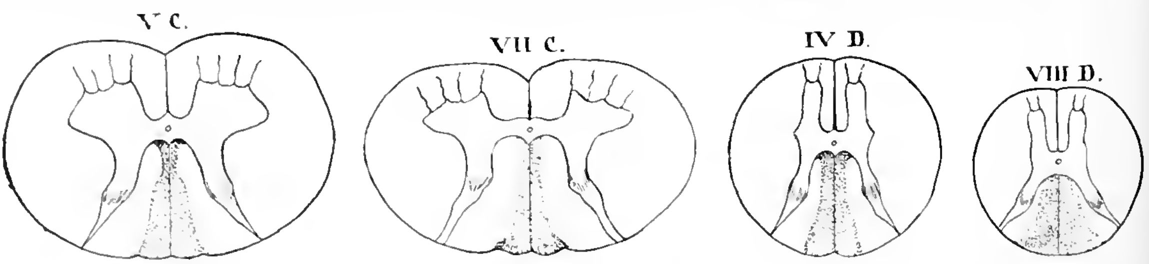
1. *The Motor Tracts* (Fig. 4412, *Py*, *AM*), two in number, which come through the anterior pyramids of the medulla, from the motor region of the cerebral cortex on either side of the fissure of Rolando. It will be remembered that the pyramids of the medulla decussate partially just at the upper limit of the spinal cord.[3] The majority of the fibres of each pyramid cross the median line to the lateral column of the spinal cord. The remainder pass directly onward into the anterior column. Those that cross over are called the crossed pyramidal tract. Those that do not cross are called the direct or anterior pyramidal tract, or column of Türck. The latter lies along the side of the anterior fissure of the cord, and is called the anterior median column (Fig. 4412, *AM*). The former lies in a triangular space in the posterior part of the lateral column, bounded by other tracts on all sides (Fig. 4412, *Py*). These motor tracts differ somewhat in size in different cords. When only a few fibres from the medulla cross over, the anterior median column is large and the opposite lateral pyramidal tract is small; but this is the exception. As a rule the lateral tract is three times the size of the anterior one. They differ also in length; for the anterior median column only extends to the upper sacral region, but the crossed pyramidal tract extends to the very lowest segment of the cord. They both send in their fibres to the anterior gray horns of the cord at all levels, and therefore decrease in size as they pass downward. They both transmit voluntary impulses from the brain to the anterior motor cells of the cord (Fig. 4412, *m*), a single nerve fibre in the motor tract carrying an impulse which reaches several groups of cells. They both degenerate downward after any lesion which cuts them off from their nutrient cells in the cerebral cortex. If that lesion is in the brain on one side, the anterior median column on that side, and the crossed pyramidal tract on the opposite side, will be degenerated in the cord. If the lesion is in the cord on one side, both motor tracts on that side will degenerate downward. If the lesion divides the entire cord, the degeneration will be bilateral in both columns. These motor tracts transmit not only voluntary impulses, but also inhibitory impulses, which hold in check the reflex activity of the spinal centres. Hence a lesion in their course produces not only paralysis, but also a loss of control over the bladder and rectum, and an increase in the spinal reflex activity.

2. *The Association Tracts* (Fig. 4415).—Each spinal segment has been shown to have functions of its own. But the different segments always act in harmony, and in hardly any act, either motor or sensory, is any segment independent of the rest. Hence a large part of the white matter of the cord contains fibres, shorter or longer, joining the various segments with one another, and associating their actions. The cell bodies which give origin to these fibres lie in the various parts of the gray matter, and send fibres both up and down in all the columns. These fibres give off collaterals in their course. The fibres lie about the anterior horns of the cord, on their different sides, making up together a large antero-lateral column which has been divided into an anterior column (Fig. 4415, *AL*), and a general lateral column, the latter having a portion between the crossed pyramidal tract and the outer surface of the gray matter which has been called the lateral limiting layer (Fig. 4415, *L*). Some association fibres also pass in the posterior columns adjacent to the posterior commissure. All these tracts are about the same size at all levels of the cord, thus differing from the motor tracts, which decrease in size from above downward, and from the sensory tracts, which increase in size from below



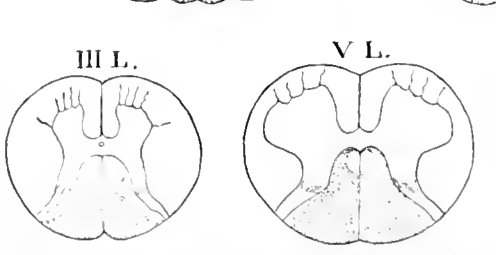


FIG. 4417. Area of Ascending Degeneration in the Posterior Columns after Compression of Cauda Equina, Involving all the Sacral and Lumbar Nerves.

upward. They degenerate but a short distance in any transverse lesion of the cord. They degenerate both upward and downward. It should not be forgotten that the anterior nerve roots pass out of the cord through the anterior column, and that many of these roots pass upward or downward for some distance before making their exit. Hence the antero-lateral column is not wholly made up of association tracts. There is no form of disease limited to the association tracts exclusively, hence it is impossible to bring any known symptoms into connection with the lesion when they are affected in a general myelitis.

3. *The Sensory Tracts.*—These occupy the posterior columns of the cord, of which there are two on each side of the posterior median septum, viz., the postero-external column, or column of Burdach, and the postero-median column, or column of Goll. They also pass in the lateral columns of the cord, in the antero-lateral ascending tract or column of Gowers, and in the direct cerebellar column. When all the nerve roots of the cauda equina, including both sacral and lumbar nerves, are compressed and destroyed, the ascending degeneration occupies a somewhat larger area than in the first case, involving both posterior columns as high as the middle of the dorsal region and a large part of the column of Goll in the cervical region (see Fig. 4417). When a transverse lesion of the cord in the dorsal region cuts off all sensory conduction from below the level of the mid-dorsal region, the area of ascending degeneration is still larger than in the first two cases, and in the cervical region involves the entire column of Goll (see Fig. 4418). When the cord is divided in the lower part of the cervical enlargement, the ascending degeneration involves a very large area, including both the entire column of Goll and a part of the column of Burdach in the upper cervical region (see Fig. 4419).

From these facts it becomes evident that the posterior nerve roots contain a number of fibres which, after entering the cord, turn upward and pass on to the medulla oblongata, each successive set from below upward lying a little in front of, and outside of, the preceding set, and gradually filling out the entire column of Goll and a portion of the column of Burdach. This is shown in Fig. 4415, *G*, *B*, at level *C VI.* In a cross-section in the upper cervical region it can, therefore, be affirmed that the fibres in the posterior median part of the column of Goll transmit sensory impulses from the legs; that the fibres in the median and lateral portion of the column of Goll transmit sensations from the thighs and pelvis; that the fibres in the anterior portion of the column of Goll transmit sensations from the body exclusive of the arms; and that the median part of the column of Burdach transmits sensations from the arms. Experimentation on animals has proven that the nerve fibres entering the cord in the posterior nerve roots, and passing upward in this manner to the medulla, degenerate upward upon the side on which they enter. There is no reason, therefore, to believe that in man there is any decussation, in the spinal cord, of the fibres thus far described. But since all sensations, except those of muscular sense, are known to cross over to, and ascend in, the opposite side of the cord in man, immediately after their entrance, it follows that the fibres thus far considered have for their function to transmit the sensations of muscular sense. And this

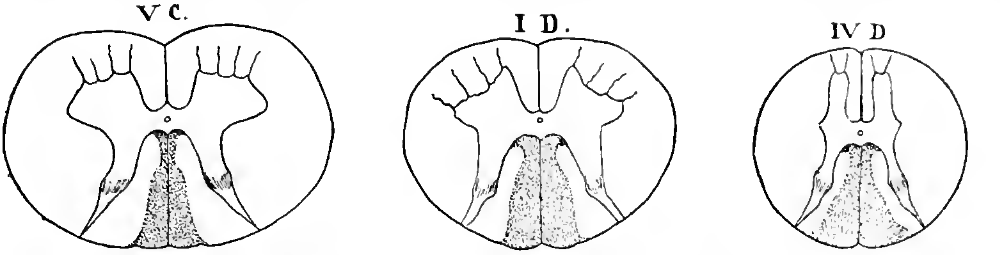

FIG. 4418.—Area of Ascending Degeneration in the Posterior Columns after a Transverse Lesion of the Mid-dorsal Region.

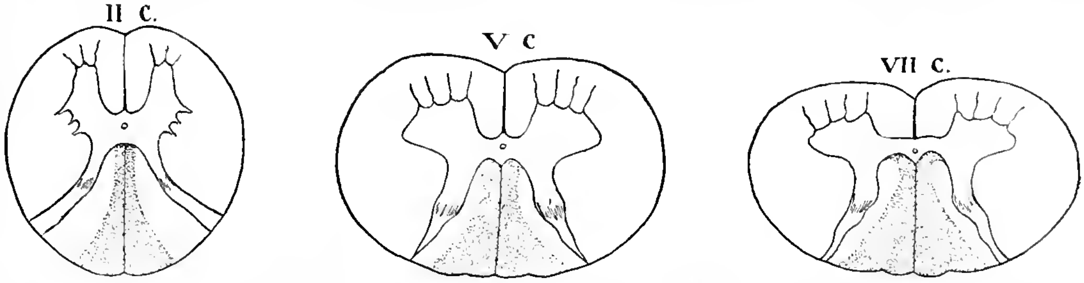

FIG. 4419.—Area of Ascending Degeneration in the Posterior Columns when the Lower Cervical Region of the Cord is Involved by a Transverse Lesion.

The column of Burdach is made up very largely of the posterior nerve roots which enter it and pass upward or downward for some distance before leaving it, to end in the posterior gray horn, or to enter the column of Goll (Fig. 4415, *B*). The column of Goll is made up wholly of long fibres extending from the posterior nerve roots to the medulla (Fig. 4415, *G*). The exact areas taken up respectively by the short posterior roots and the long fibres differ greatly at different levels, and they have only recently been determined by a study of the tracts degenerated after transverse lesions at different levels. These recent investigations deserve a moment's notice.

If the posterior nerve roots are divided between the posterior spinal ganglia and their entrance into the cord, an ascending degeneration occurs in the cord. It is by observing the course of this ascending degeneration that the upward continuation of the sensory nerves has been determined.[4] The area of the posterior columns of the cord which degenerates upward differs in different cases. When the sciatic nerve roots alone are divided, or the sacral portion of the spinal cord is destroyed, the ascending degeneration occupies a large area of the posterior columns in the lumbar region, a smaller area in the dorsal region lying wholly in the column of Goll, and the posterior median portion only of the column of Goll in the upper dorsal and cervical regions (see Fig. 4416).

conclusion is further established from the facts gathered from the pathology of locomotor ataxia. For in this disease, in which the muscular sense is the one most seriously impaired, the same areas of degeneration are found. There is, first, the sclerosis in the root zone of the column of Burdach, involving the nerve roots in it, and secondly, the secondary degeneration in the column of Goll, whose extent is determined by the extent of the primary lesion. The higher the primary lesion advances, the greater the area of the column of Goll involved. Since cases have been observed in which the sensations of touch, of pain, and of temperature, and of the muscular sense, have been affected singly, it follows that the tracts conveying these sensations must be separate from one another. The fibres so far described terminate in the nuclei of Goll and Burdach. But from these nuclei the fibres of the interolivary tract and lemniscus arise, fibres which are known to decussate in the sensory decussation of the medulla, and are known to transmit sensations of muscular sense exclusively. Hence the conclusion seems warranted that the sensory tract for muscular sense lies in the column of Goll for all parts below the arms, and in the median part of the column of Burdach for the arms.

With regard to the sensory tracts for touch, pain, and temperature, our knowledge is much more indefinite. These sensations enter the cord by the posterior nerve roots. But these roots do not send all of their fibres upward in the path already described. And if the area of the cord occupied by the column of Goll in the cervical region be compared with the entire area of the posterior nerve roots, it will be seen that a mere fraction of the fibres entering the cord by these roots ascends to the medulla. The large remainder terminate in the cord. Anatomists describe various manners of termination. Some fibres end directly in the posterior gray horn; others pass through it to reach the anterior gray horn; others, still, cross over through the posterior gray decussation to the other side of the cord. Many fibres enter the column of Burdach and pass directly through it to enter the gray matter in the vicinity of the vesicular column of Clarke; others ascend some distance in the column of Burdach before they enter the gray matter, and a few turn downward in the column of Burdach before ending in the gray matter. The fibres turning downward are collected into a small bundle, named the comma-shaped bundle of Schultze, from the shape of its area in cross section. From the fact that general myelitis involving the posterior gray matter is always attended by sensory symptoms, it is concluded that many sensations are sent to the cells of the posterior horns. From the cells in the posterior gray matter some nerve fibres pass backward into the columns of Goll and Burdach, and mingle with the fibres of those columns, presumably ascending with them to the medulla. It is not improbable that these fibres transmit sensations of touch. Even in the most extreme cases of secondary ascending degeneration in the posterior columns, after division of the nerve roots, many fibres in those columns escape. It is therefore certain that some of the fibres making them up have their origin and nutrient cells in the gray matter of the posterior horns, rather than in the posterior spinal ganglia. Hence the facts do not exclude the possibility of the transmission upward of sensations of touch in the posterior columns of the cord after such sensations have crossed the median line in the gray matter. And that they are transmitted in this region the older physiological experiments established. Other physiological experiments point to a transmission of sensations of touch in the lateral columns of the cord. And Gowers has established the existence of a tract in the periphery of the antero-lateral column, lying anterior to the direct cerebellar tract, which degenerates upward after transverse lesions. This is called the antero-lateral ascending tract. Its fibres arise from cells in the gray matter (Fig. 4414, *c*), cross to the other side, passing through the antero-lateral column, and turn upward in this column. This column ascends through the antero-lateral part of the medulla and pons. Some of its fibres have been traced into the lemniscus and some into the cerebellum. There are other fibres which arise from cells in the posterior gray matter of the cord, and crossing to the opposite side, ascend in the antero-lateral column (Fig. 4414, *X*, *AL*) of the cord.

The sensations of temperature and pain are uniformly preserved or lost together, hence it is concluded that they pass in the same tract. No definite position can be assigned as yet to that tract. In syringomyelitis, in which the lesion is limited to the central gray matter of the spinal cord between the anterior and posterior horns, a loss of temperature and pain sensations in all parts below the level of the lesion has been observed, and it has been concluded that these sensations are transmitted by the gray matter. Gowers believes that they pass in his antero-lateral tract, but the conclusion rests upon too small a number of observations to be hastily adopted. It seems to be likely that the transmission of sensations through the cord is not merely attained by these long tracts, but that they pass chiefly through a series of the association tracts already described, which are scattered through all the columns. A given sensation sets up many reflex and vaso-motor impulses in the cord in addition to being sent to the brain to awaken a perception. Hence it is likely to pass by a broken rather than a continuous tract. But the exact course of sensory impulses is not yet determined with accuracy.

4. *The Direct Cerebellar Column.*—The last column of the cord to be described is one lying upon the outer surface of the lateral column, and extending from the lower dorsal region to the corpus restiforme of the medulla, and thence to the cerebellum. Its termination in that organ has led to its name—the direct cerebellar tract. It is made up of fibres whose origin is in that column of cells which lies in the median part of the posterior horn known as the vesicular column of Clarke (Fig. 4414, *c*, *DC*). The cells are only found in the dorsal region, hence all the fibres in this tract come from the dorsal segments of the cord. They reach the lateral periphery of the cord by passing diagonally through the lateral column. They are supposed to transmit sensations upward from the Clarke column of cells to the cerebellum, because they degenerate upward after a transverse lesion of the cord. The function of both the cells and the tract is uncertain. From recent investigations by Gaskell, however, it seems probable that the vesicular column of Clarke is connected with the vaso-motor and sympathetic nervous systems by means of very small nerve fibres extending from the sympathetic ganglia into the cord. If this is so, the function of the direct cerebellar tract is to transmit those rather indefinite sensations from the viscera, or to act as a tract for unconscious sensations or motor impulses necessary in a central regulation of visceral and vascular action. The hypothesis that they convey muscular-sense sensations from the trunk is hardly warranted, since these must be of little importance in lower animals, who do not walk erect—in which animals, however, this column is well developed.

II. Symptoms Leading to the Diagnosis of Local Lesions in the Spinal Cord.—Such being the functions of the various parts of the spinal cord, it remains to discuss the symptoms arising when various parts are diseased. And it will be as well to approach this subject from the side of the symptoms rather than from that of the lesion, since it is the object to determine the lesion in any case.

1. *Spinal Paralysis.*—The motor tract conveying voluntary impulses from the brain to the muscles consists of two elements: first, the cerebro-spinal element, and, secondly, the spino-muscular element. Each element consists of a set of nerve cells and their outgoing fibres, which not only transmit impulses from the cells, but are nourished by them. The cells of the cerebro-spinal element lie in the cerebral cortex. Their fibres make up the motor tract through the brain and through the direct and crossed pyramidal tracts of the spinal cord.[5] These fibres terminate about the motor cells of the anterior horns of the cord at various levels, some of them reach-

ing its very lowest part. Any lesion in the cells of the cortex, or in the course of the fibres, which cuts them off from those cells, results in the degeneration downward of the cerebro-spinal element to its termination in the motor cells of the spinal cord. The *first form of spinal paralysis* is due to a lesion at the spinal part of this cerebro-spinal element of the motor tract. If the cord is divided by a transverse lesion at any point, the function of this element of the motor tract is thereby suspended. As a result, voluntary motion is arrested in the parts below the lesion. If the lesion involves but one-half of the cord, it is the limbs on the side of the lesion which are paralyzed. If it involves the entire cord, both sides are paralyzed. The extent of the paralysis depends upon the level of the lesion; the higher the lesion the more extensive the paralysis. The degree of the paralysis will depend on the character of the lesion, slight compression of the cord at one point by a tumor, or a pachymeningitis, or a projecting vertebra, being followed by some stiffness of movement and rigidity of the muscles, with weakness, rather than by absolute loss of power in the parts below the level of the pressure. The cerebro-spinal element of the motor tract also transmits the inhibitory impulses which continually keep the spinal reflex and automatic mechanisms in check. A lesion of this tract, therefore, produces not only weakness and paralysis, but also increase of the deep reflexes, and impairment of control over the bladder and rectum. The muscular action of the limbs, being no longer controlled by the brain, is governed wholly by the centres in the spinal cord. These act in response to sensory impulses, or spontaneously, without check, and hence the preponderating strength of flexor over extensor muscles tends to produce a position of adduction and flexion of the limbs which are paralyzed, and a heightened muscular tone, with tendency to rigidity. The nutrition of the paralyzed muscles may suffer somewhat from disuse, and from the attendant vaso-motor paresis, but no rapid atrophy is noted when the cerebro-spinal element of the motor tract is alone involved. And it is also to be noted that the paralysis affects the entire limb or limbs, and not any special group of muscles. In these cases the electric contractility remains normal in the paralyzed limbs.

A typical example of this form of spinal paralysis is seen in compression of the spinal cord, below the lesion, and in lateral sclerosis or spastic paraplegia (*q.v.*).

The *second form of spinal paralysis* is due to a lesion in the spinal part of the second element of the motor tract, viz., the spino-muscular element. This consists of the cells of the anterior gray horns of the cord, and the anterior nerve roots which pass out through the anterior columns of the cord. Destruction of the cells suspends both voluntary and reflex motor impulses to the muscles. The cells not only control the motion, but also the nutrition, of the nerves to which they give origin, and of the muscles to which these nerves go. Therefore destruction of the cells produces atrophy of the muscles with which they are connected. If the destruction is gradual, the atrophy is gradual, as in progressive muscular atrophy. If the destruction is rapid, the atrophy is rapid, as in infantile paralysis. The degree of the atrophy depends upon the degree of destruction of the group of cells which govern the particular muscle affected. If the group is wholly destroyed, the muscle becomes totally atrophied. In addition to paralysis with atrophy there is in the second form of spinal paralysis a change in the electric reaction of the paralyzed muscles. They lose their contractility to the faradic current, and alter their contractility to the galvanic current, responding in a sluggish manner, and to the positive more readily than to the negative pole. This is called the reaction of degeneration (*q.v.*).

The extent of the paralysis depends upon the extent of gray matter affected, and a reference to the table of the localization of functions already given (page 340) will enable one to determine the effect of a lesion at any particular segment, or through a group of segments, of the spinal cord. A typical example of the second form of spinal paralysis is found in infantile paralysis or poliomyelitis anterior. The muscles in this disease are paralyzed, atrophied, exhibit the reaction of degeneration, and lose their reflex excitability. An entire limb is rarely affected, certain groups of muscles being usually paralyzed together, *e.g.*, the deltoid, biceps, brachialis anticus, and supinator longus (upper arm group); or the extensors of the wrist and hand muscles (lower arm group); or the glutei and thigh muscles (thigh group); or the anterior tibial and peroneal groups of the leg (leg group). The muscles affected are not those which are supplied by a single peripheral nerve—a fact which enables a diagnosis between a lesion in the spinal cord and a lesion in a peripheral nerve to be easily made—but those which act together to produce a definite physiological act.

The contrast between these two forms of spinal paralysis can be seen at a glance in the following table:

First Type of Spinal Paralysis.	Second Type of Spinal Paralysis.
Lesion in pyramidal tracts.	Lesion in anterior gray horns.
Paralysis usually on both sides equally, in legs or in legs and arms, never in arms alone.	*Paralysis* may be limited to any single limb, and rarely affects both limbs equally.
All muscles are about equally affected. No muscles are entirely normal.	Certain groups of muscles only are affected. Others escape wholly.
Muscular tone is heightened.	Muscular tone is diminished.
Tendency to rigidity appears.	Muscles are relaxed.
Reflex excitability is increased.	Reflex excitability is lost.
Atrophy is absent or is slight, and merely due to disuse, hence is gradual in progress. It affects the entire limb.	*Atrophy* is always present in the paralyzed muscles. It advances rapidly, and may become extreme.
Electric contractility is unchanged.	*Electric contractility* is changed. Reaction of degeneration is present within two weeks of the onset.
Vascular tone is diminished; cyanosis and œdema may occur.	*Vascular tone* is diminished, but œdema does not occur.
Paralyzed limb is cold, and sweat may be increased.	Paralyzed limb is cool, but sweat is not increased.
Trophic disturbances in the skin are not infrequent.	*Trophic disturbances* in the skin do not occur.
The control over the bladder and rectum may be diminished or lost.	The control over the bladder and rectum is not impaired.
Example: Spastic paraplegia.	Example: Infantile paralysis.

The *third type of spinal paralysis* is a combination of the first and second types. When a transverse lesion of the spinal cord entirely destroys a single segment, it produces paralysis of the first type in the parts below the level of the lesion by cutting off the tracts to those parts, and paralysis of the second type at the level of the lesion by destroying the gray motor cells at that level. The general effect of such a lesion depends entirely upon the level at which it occurs; the higher the lesion, the greater the extent of the first type of paralysis. The distribution of the second type will depend on the level of the segment involved. The greater the extent of the lesion at the level affected, the greater the extent of the second type of paralysis. An example of this is also found in amyotrophic lateral sclerosis. When a longitudinal lesion of great extent occurs—such as the general destruction of the cord in general myelitis—the second type of paralysis is the form which is found, but all the muscles are affected, not merely a few groups. The bladder and rectum are also affected, and bedsores are frequent.

In any case of spinal paralysis, if the electric condition of the muscles paralyzed be ascertained by the aid of a faradic battery, and the diagnostic points here brought together be applied, reference to the table of the localization of functions will enable the exact level of the lesion to be determined.

Spinal Anæsthesia.—The course of the sensory tract in the spinal cord is still somewhat imperfectly understood. It is known that all sensory impulses reach the spinal cord through the posterior nerve roots, which partly enter the apex of the posterior horn, and partly enter the column of Burdach, and pass upward as already described. The sensations of muscular sense ascend on the same side as that on which they enter. Those of touch, temperature, and pain cross over, as soon as they

EXPLANATION OF PLATE LII.

The segments of the spinal cord are numbered: C_{I} to C_{VII}, D_{I} to D_{XII}, L_{I} to L_{V}, S_{I} to S_{V}; and these numbers are placed, in the plate, on the region of the skin supplied by the sensory nerves of the corresponding segment. In order to determine, in any given case of spinal-cord disease, the level of the cord affected, it is necessary to test the sensations and to compare the area of anæsthesia with the diagram here given. It is to be remembered, however, that the skin of the body is plentifully supplied with sensory nerves which anastomose freely at their terminations, and the researches of Sherrington have demonstrated that each part of the skin is supplied with sensory nerves from two adjacent segments of the cord. Hence a condition of anæsthesia in the skin indicates a suspension of function of two segments of the cord at least, for if one segment alone were affected the segments above and below it would be capable of supplying the skin with sensation.

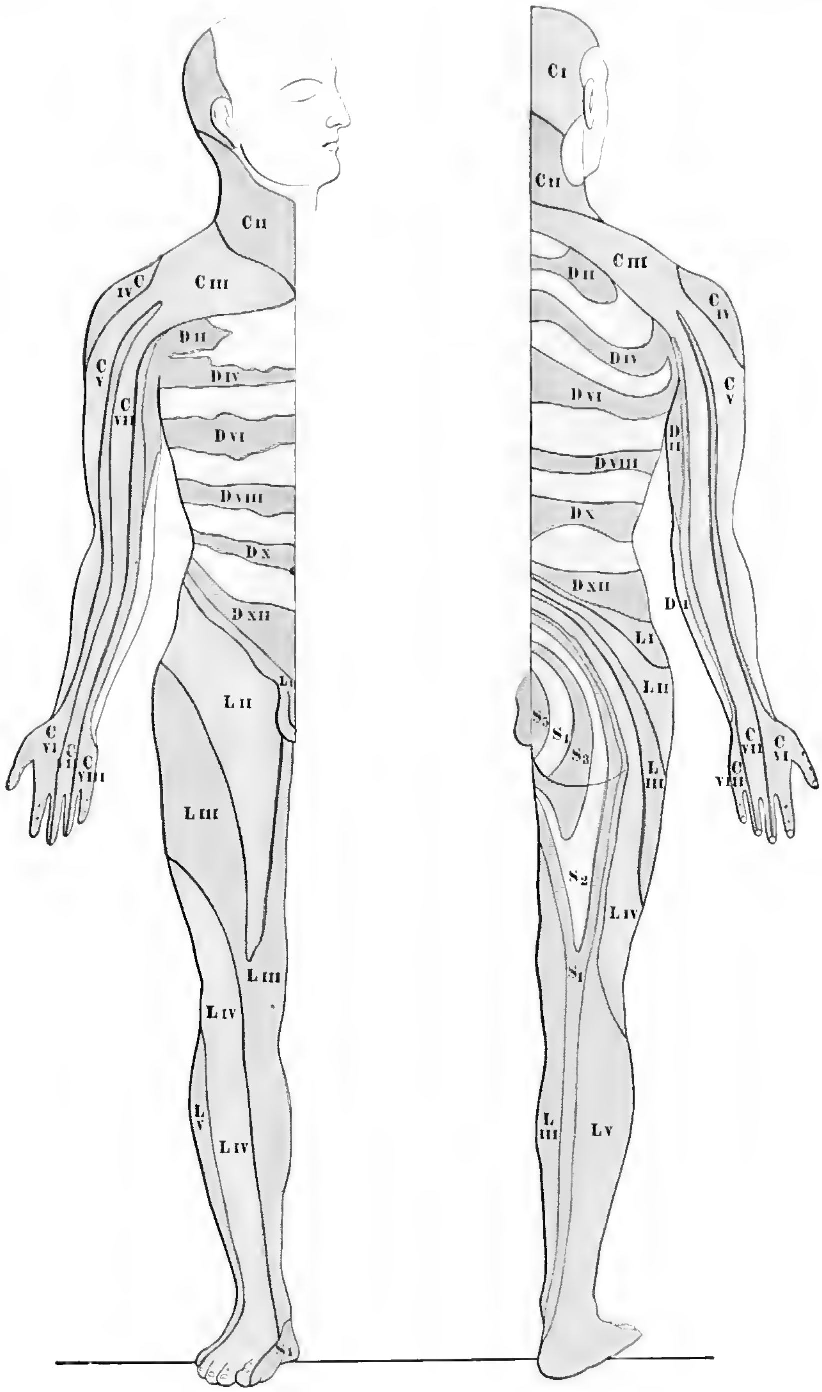

PLATE SHOWING THE AREAS OF THE SURFACE OF THE BODY WHICH ARE RELATED TO THE VARIOUS SEGMENTS OF THE SPINAL CORD

c, cervical: *d*, dorsal: *l*, lumbar: *s*, sacral. When a segment of the cord is destroyed the surface of the body is anæsthetic in the area corresponding to that segment.

(From Dr. M. Allen Starr)

any one of these acts are similar to those underlying the simple spinal reflex, and the same lesions arresting it may arrest these acts. But the result of such arrest is more serious, for, in the case of the bladder or rectum, retention or passive incontinence of urine or fæces may follow. And if the inhibitory impulses from the brain to these centres are cut off, the voluntary control over these mechanisms is impaired, and the acts cannot be initiated voluntarily, and active incontinence may result. The location of the bladder and rectal mechanism is in the lower sacral region. Hence, when this part is the seat of a lesion, or is cut off from the brain by a lesion at a higher level in the motor tract, incontinence, either active or passive, or retention, may result.

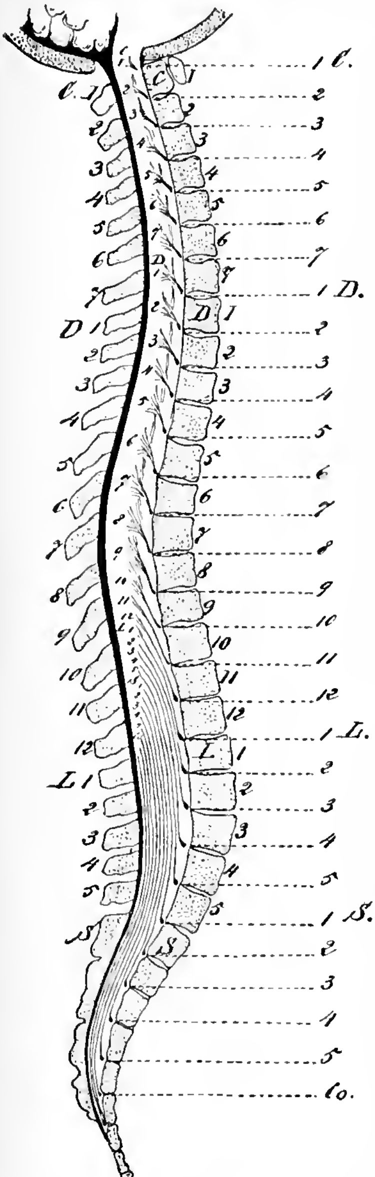

FIG. 4420.—Relations between the Segments of the Spinal Cord and their Nerves and the Bodies of the Vertebræ. (Gowers.)

A part of the automatic mechanism of respiration is governed by the cervical and dorsal regions of the cord, and is interfered with in disease in those regions. Lesions of the upper cervical region paralyze the diaphragm and thus cause death.

DISTURBANCE OF VASO-MOTOR AND TROPHIC FUNCTIONS of the cord may occur from various forms of lesion. Anterior poliomyelitis produces atrophy of the muscles paralyzed, and a sufficient affection of the vaso-motor system to cause objective, as well as subjective, coldness in the limb; and when the lesion lies deep in the anterior horn, an arrest of development of the bones of the limb affected. General myelitis is usually associated with a tendency to bedsores upon the parts exposed to pressure, which cannot be avoided by the most scrupulous cleanliness, and to cystitis, and these are ascribed to a disturbance of trophic impulses to the skin and bladder. Posterior sclerosis is sometimes associated with trophic changes, such as perforating ulcers, joint affections (Charcot's arthropathies), and eruptions on the skin. In a few cases of leprosy serious lesions of the posterior gray horns have been observed. In general myelitis there is a partial vaso-motor paralysis, indicated by cyanosis, sluggish circulation, œdema, and coldness, with abnormal sweating in the paralyzed parts. But any definite statement regarding the exact localization of vaso motor or trophic functions in the spinal cord cannot be made as yet. And recently many vaso-motor and trophic symptoms, formerly supposed to be due to spinal lesions, have been found to be produced by disease in the peripheral nerves. It is, however, established that trophic lesions are most frequently observed when the gray matter of the spinal cord in the vicinity of the central canal, including the vesicular column of Clarke, is the part diseased; or when all sensation is cut off from the paralyzed limbs by a transverse lesion.

The regulation of urinary excretion is presided over by a centre in the medulla, and the nerve tract thence to the liver and kidneys is traced through the cervical region of the spinal cord to the first dorsal segment, where it enters the sympathetic chain of ganglia. A lesion in the lateral column of the cervical cord, by involving this tract, may cause a vaso-motor paralysis of either the liver or the kidneys. In the former case diabetes mellitus is produced; in the latter, diabetes insipidus results. It is therefore necessary, in lesions of the spinal cord, to examine the amount and constituents of the urine.

In any case of spinal disease in which it is desirable to localize accurately the lesion, it is suggested that a written summary of the symptoms be compared with the table of localization of the functions of the cord, when it will become evident, by contrasting the normal with the abnormal conditions, what part of the cord is affected. As Bramwell justly observes, "the essence of the clinical examination of the spinal cord consists in the systematic and separate examination of each spinal segment, by observing the motor, sensory, reflex, vaso-motor, and trophic conditions of its body area." Such an examination will lead to accurate diagnosis of local lesions.

But one point remains to be mentioned, that is, the relation of the various segments of the cord to the bodies and spines of the various vertebræ. As the cord extends only to the level of the second lumbar vertebra, its various segments do not lie opposite to the vertebræ from which they are named. The accompanying diagram of Gowers (Fig. 4420) displays the mutual relation between the segments and their nerves, and the bodies of the vertebræ, and no further description is needed.

SPINAL-CORD DISEASES: FRIEDREICH'S (HEREDITARY) ATAXIA.—The condition known as Friedreich's or hereditary ataxia was first described by Friedreich in 1861, and a detailed account published by him in 1863, with three autopsies. In 1876 he published a further paper on the subject, with a description of three new cases. From this time on, through the investigations of Schultze, Rütimeyer, Dejerine and others, the affection came to be clearly recognized as an hereditary disease of childhood, affecting chiefly the spinal cord, and characterized by a type of ataxia hitherto undescribed. W. Everett Smith in 1885 published an important paper on the subject of "hereditary or degenerative ataxia," in which he described six cases in one family, with an autopsy. He was able at that time to collect fifty-seven cases from the literature. In 1890 Ladame made a critical digest of the subject, published in translation in *Brain*, in which he summarized the knowledge up to that year, and gave full bibliographical references. Nine autopsies only had been recorded, and five of these were in Friedreich's own cases. Oscar Richardson has recently described the post-mortem findings in a second case from the family reported in 1885 by W. Everett Smith.

Pathological Anatomy.—The spinal cord has usually been found small and somewhat imperfectly developed, which is in accordance with the apparently hereditary

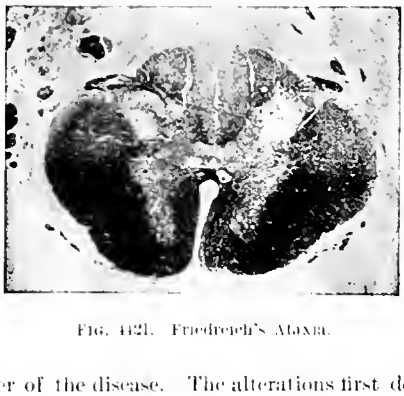

Fig. 4421. Friedreich's Ataxia.

character of the disease. The alterations first described by Friedreich consisted in a degeneration of the dorsal tracts, atrophy of dorsal roots, and certain changes, slight in degree, in several peripheral nerves. Later study has shown that wider areas of the white matter are involved than was at first supposed, and that the gray matter also takes part in the degenerative process, though to a much less marked degree. Degeneration of the dorsal tracts to a very considerable extent is constant, with a probable constant accompaniment of degeneration of dorsal nerve roots, giving an appearance wholly analogous to tabes, and leading to the assumption that the primary sensory neurone, as such, is involved. The direct cerebellar tract is degenerated; Gowers' tract and Lissauer's bundle may be. Various observations have been made regarding the motor pyramidal tracts, and it is still in dispute whether they are in themselves involved as neurone systems in the same way that the dorsal tracts are. Degeneration in the region of the pyramidal tracts decreases from below upward, and disappears (Leyden-Goldscheider) at the lower level of the oblongata. In Richardson's case, the pathological anatomy of which he has described and which he has given me the opportunity of studying, the following lesions of the white matter were definite: degeneration of dorsal columns throughout the cord, and of dorsal nerve roots in the lumbar region; degeneration of pyramidal tracts, of somewhat lessening intensity toward the upper portions of the cord, including the uncrossed tracts in the cervical region; degeneration of direct cerebellar tracts, and in less degree of the region of Gowers' antero lateral ascending tracts (see Fig. 4421).

In the gray matter the cells of Clarke's columns have, in certain cases, shown degenerative changes, along with the myelinated fibres of that nucleus. Alterations in other portions of the gray matter of the cord have been described, but are of somewhat doubtful character. Very few observations on the peripheral nerves have been made, but certain degenerations have been described which would be in accord with the theory of a neurone degeneration. The type of lesion in the cord is similar to that found in other sclerotic processes, an overgrowth of neuroglia following a greater or less degree of destruction of myelinated fibres. The theory of a primary overgrowth of neuroglia has not been generally accepted. Alterations in the blood-vessels in degenerated areas occur, and also have been described in the pia and nerve roots, but no characteristic significance is to be attached to the changes found.

The cause of the foregoing anatomical alterations has, in general, been sought in a defect of development, of hereditary character, leading to early degenerative changes in the spinal cord. The distribution of these changes in the relatively few cases examined post mortem has led certain observers to the assumption of a combined systemic disease, which gains weight from the fact that the disease occurs as a family affection, and does not apparently depend upon faulty blood states or vascular conditions within the cord itself. Certain cases, however, do not show a sharply systematized degeneration, although the lesions are always of a quasi-systemic character. The study of Richardson's case, to which I have already alluded, leads to the conclusion that neurones, as systems, are involved, though it cannot be said with certainty that groups of neurones, of which our knowledge is as yet deficient, may not also be degenerated. In support of this assumption is the distinct degeneration of dorsal nerve roots and of direct pyramidal tracts, as well as the characteristic degenerations of the recognized neurone systems. The most satisfactory conception of the disease, therefore, is that in congenitally defective nervous systems early degenerations of a systemic or quasi-systemic character take place, chiefly limited to the spinal cord, which progress exceedingly slowly, ultimately leading to characteristic motor and sensory disorders.

Symptomatology.—The most conspicuous feature of the disease is a characteristic inco-ordination, which is best described as a combination of a tabetic and a cerebellar ataxia. The gait is uncertain, slow, highly inco-ordinate, and accompanied by a considerable degree of swaying from side to side. Static ataxia is well marked in the extremities and head after the disease has progressed beyond its initial stages. The Romberg sign (swaying with the eyes closed) is much less constant than in tabes, but has been described in certain cases. A further characteristic motor disturbance is peculiar involuntary, chorea-like movements involving the head, which persist during rest, but are increased on intended movement. At times a definite, so-called intention tremor may develop. True paralyses do not occur in the long course of the disease, except in the late, more or less helpless stage, when weakness of muscle groups may develop, and finally paraplegia with contractures, which renders locomotion impossible. Another very constant motor disorder, but not one of the earliest signs, is nystagmus, which is usually not present when the eyes are at rest, but may be elicited by fixation, particularly in a lateral direction. This sign should, however, be interpreted with caution. Disturbance of speech is a further important sign; it is slow, difficult, irregular in utterance, and hard to understand. The tongue is tremulous and is the seat of twitching movements, suggesting, in conjunction with the speech disorder, disturbances of co-ordination similar to those observed in the extremities and possibly bearing some analogy to multiple sclerosis.

For reasons not easy of explanation the sensory sphere suffers in very slight degree, in marked contrast to tabes. With but few trifling exceptions muscle sense and skin sensibility, as well as the special senses, have been found unimpaired. The occasional occurrence of sharp pains and abnormal subjective disorders of sensibility in the extremities are of interest only because of their rarity. In view of the constant extensive degeneration of sensory areas in the cord, and the high degree of inco-ordination early developed in the disease, this lack of objectively demonstrable sensory disorders must be regarded as one of the striking peculiarities of the disease. An appeal to vicarious or certainly added function in neurones remaining intact in an affection of very gradual progression, may be suggested by way of explanation.

The superficial skin reflexes, the pupil, bladder, and rectal reflexes show essentially no alteration, whereas the loss of knee-jerk is constant in all well-developed cases. Trophic and general vaso-motor disturbances have seldom been observed, and the sexual function remains unimpaired. A frequent occurrence, which has not received as yet a satisfactory explanation, is a deformity of the foot of the nature of a talipes equinus, or equino-varus, often with an elevated arch, shortening of the foot as a whole, development of so-called claw-foot, with particularly strong dorsal flexion of the great toe. Scoliosis is also an occasional accompaniment. Cerebral symptoms do not occur, except vertigo, and in the later stages of the disease a general impairment of the mental faculties.

Diagnosis, Prognosis, and Course.—The symptoms,—early ataxia, loss of knee-jerk, choreic movements, clubfoot, disorders of speech, nystagmus, with progressive helplessness, beginning before the sixteenth year—point unmistakably to Friedreich's ataxia. With the possible exception of so-called cerebellar ataxia, tabes, and multiple sclerosis, the differential diagnosis from other organic cord affections should present no difficulties. The grouping of symptoms given above is usually well marked and is unique.

The course of the disease is steadily progressive, beginning in childhood and lasting for from twenty to forty years or even longer, death ultimately being due, in many cases, to intercurrent disease, or to cystitis or decubitus, induced by the cord changes.

Etiology.—The actual cause of the disease remains obscure. The facts that it occurs in children before or at the age of puberty, that cases have frequently been observed in the same family, though by no means constantly, that the cord, post mortem, gives indications of faulty development, have led to the suggestion that it is due to hereditary influences. Further than this nothing of value has been found. An appeal to syphilis, alcohol, or various neuroses or psychoses in ancestors does little to elucidate the matter. Nor is it profitable in a disease of this character to lay stress upon possible exciting causes. As in all disease, there is a predisposition, which is rather the statement of a self-evident fact than an explanation, so long as we remain in complete ignorance of what constitutes predisposition. The fact of importance is that in certain families the affection has appeared in several members. As given by Gowers, sixty-five cases were distributed in nineteen families, and ten occurred in one family. Sporadic cases are probably more frequent than is ordinarily supposed. It has been a frequent observation that many cases occur in one generation in families in which the parents or ancestors were not victims of the disease—so-called indirect inheritance. The affection is, therefore, to be regarded as one of the group of "family diseases."

Treatment.—In the present state of our knowledge, treatment must remain essentially unavailing, except as directed toward the amelioration of symptoms. Systematic exercises (Frenkel), avoidance of overexertion, careful attention to general hygiene, good food, and fresh air, with such drugs as are symptomatically required, must constitute our main reliance. *E. W. Taylor.*

SPINAL-CORD DISEASES: HEMORRHAGE IN THE CORD.—(Synonyms: Hæmatomyelia; spinal apoplexy.) Hemorrhage in the spinal cord is very rare in comparison with hemorrhage in the brain. When it occurs it is usually of small extent. This is not extraordinary when the size of the organ and the firmness of its connective tissue sheath, and the low pressure in the spinal arteries, are considered. As a rule, the clot in the spinal cord is long and narrow. It destroys a considerable part of the cord at one segment, and extends into the segments above and below, injuring these to a less extent. The clot is usually found in the gray matter of the cord, most frequently in the anterior horns, then in the posterior horns, and rarely in the white columns. Sometimes the surface of the cord is broken and the blood infiltrates the pia mater. Occasionally a large number of small clots are found at different levels. As the patient rarely dies at once of hemorrhage the clot is usually found in a state of decomposition, and the cord around it is infiltrated with blood cells, pigment granules, and hæmatin crystals. If the hemorrhage is capillary—as sometimes occurs—it is detected by the presence of pigment and crystals among the degenerated spinal elements. Around the clot the spinal cord is usually found in a state of softening, which is red in recent cases, and white when the process has been a long one. At a post-mortem examination the question sometimes arises whether the condition found is a myelitis with secondary hemorrhage, or a hemorrhage with secondary myelitis. In the former case the microscopic examination shows a greater preponderance of granular corpuscles and leucocytes, a greater degree of degeneration in the nerve cells, and a greater extent of connective-tissue growth. Secondary degenerations upward and downward from the segment destroyed, and secondary degenerations in the motor nerves from the segment affected to the muscles, are observed after spinal hemorrhage as after myelitis. The meninges are rarely involved.

Etiology.—Spinal hemorrhage is met with in males more frequently than in females, and in youth and middle age most often. The predisposing causes are chronic changes in the general arterial system, hemorrhagic diathesis, purpura, and myelitis of the spinal cord. The exciting causes are injuries to the vertebral column and cord and extreme muscular effort, also the sudden exposure to a marked change of atmospheric pressure. A number of cases of cervical hemorrhage have occurred from sudden bending forward of the neck.

Symptoms.—As a rule, the symptoms begin suddenly, and the patient is seized in a moment with complete paraplegia and intense pain in the back at the level of the hemorrhage, and shooting pains in the body and stiffness of the spine. A spinal apoplexy usually comes without any warning, after a sudden effort. When premonitory symptoms have existed for a few days it is probable that the case is one of acute myelitis. The extent of the paralysis depends upon the level of the lesion. (See article on *Spinal-Cord Diseases: Diagnosis of Local Lesions in the Cord.*) If it is located in the lumbar or dorsal region, the lower half of the body only is involved; if in the cervical region, the arms are affected as well. The hemorrhage is rarely so very limited as to affect one extremity only, but it is not infrequently the case that the symptoms are more marked on one side, and in some cases the symptoms of a Brown-Séquard type have occurred. The paralysis is total, no voluntary motion is possible, the limbs are relaxed and never rigid. The muscles do not atrophy or present any change in the electric reactions, excepting those which are supplied with nerves from the segment which is destroyed by the hemorrhage. The condition of the reflex action depends upon the seat of the lesion: it is suspended at the level of the hemorrhage, and increased in the segments below it. If the hemorrhage is in the cervical region there is an atrophic flaccid paralysis of the arms and a spastic paralysis of the legs. In such a case there may be ventro-pupillary symptoms also.

If the hemorrhage is confined to the central gray matter and the patient survives, the symptoms may resemble those of syringomyelia. The bladder and rectum are uniformly paralyzed, and various forms of incontinence of urine and fæces result, dependent upon the seat of the lesion. If this is situated high up in the cord, the viscus may empty itself occasionally, as the need arises, unconsciously to the patient and independently of his effort or control. If the lesion is low down (below the eleventh dorsal segment), there is usually retention of urine and fæces, or complete relaxation of the sphincters. Cases sometimes occur of hemorrhage into the lower sacral region and conus terminalis from injuries; and in such cases there may be paralysis of the bladder and rectum only, with a small heart-shaped area of anæsthesia about the anus and buttocks. Vasomotor paralysis accompanies the voluntary paralysis, and results in cyanosis and coldness of the paralyzed limbs, and predisposes the parts to the development of bedsores. The latter appear, very soon after the hemorrhage, on the prominent parts of the body which are subjected to pressure; voluntary movements to relieve such pressure, or reflex movements for the same purpose, being impossible on account of the lack of power and of sensation, for complete anæsthesia and analgesia exist in the paralyzed limbs from the outset. Pain in the back, which occurs at the time of hemorrhage, does not usually persist. The danger in these cases is from the occurrence of bedsores, or of cystitis, and consequent infection from these sources, with the development of septic fever. If the hemorrhage involves the respiratory centres in the upper cervical region, sudden death takes place. This is rare.

The symptoms described are those of a severe hemorrhage, sufficient to destroy one or more segments of the cord. As a rule these symptoms gradually subside as the pressure of the clot is removed and the only permanent symptoms are those which are due to the actual destruction of the spinal elements, viz., limited atrophic paralysis and localized anæsthesia. Dissociated anæsthesia, viz., a loss of the senses of pain and temperature with preservation of the sense of touch, is not an uncommon result in the parts below the segment affected. If the clot is a small one, however, the symptoms may be more limited and less serious, partial anæsthesia and localized paralysis, with atrophy, being the result. This, however, is the exception. Capillary hemorrhages give rise to widespread symptoms, which so closely resemble those of diffuse myelitis that differential diagnosis is impossible.

The PROGNOSIS is very bad in spinal apoplexy, for a destruction of the spinal elements cannot be recovered from. The patients either die suddenly, or die of complications, or linger on for months with all the symptoms of chronic myelitis. In the lighter cases they may recover sufficiently to get about, but some evidences of the hemorrhage in the form of local paralysis or areas of anæsthesia always remain.

The DIAGNOSIS is usually easy, the sudden onset of total paraplegia being characteristic. In meningeal hemorrhage the paralysis is less marked than the spasms, and anæsthesia is rare. In poliomyelitis anterior there is marked constitutional disturbance, with fever, before the paralysis begins, and anæsthesia is not present. In acute central myelitis the onset is more gradual, the symptoms develop successively, they extend gradually to other parts, and fever is usual.

TREATMENT cannot reach the disease, but the patient should be kept absolutely quiet in the prone posture in bed, ice should be applied to the spine, and ergot should be given freely. The subsequent treatment resolves itself into care of the patient, and such measures as are used in the management of a case of chronic myelitis.

M. Allen Starr.

SPINAL-CORD DISEASES: LATERAL SCLEROSIS.

—(*a*) PRIMARY LATERAL SCLEROSIS.—(Synonyms: Spastic spinal paralysis; Tabes dorsal spasmodique.)

Definition.—The disease is characterized by a gradually progressing paralysis, which begins in the lower extremities, is accompanied by greatly exaggerated tendon reflexes, muscular rigidity, and contractures, and is not attended by sensory, trophic, or visceral symptoms. The anatomical basis is supposed to be a primary sclerosis of the antero-lateral columns.

Etiology.—We know very little of the causes of the disease. It occurs chiefly in adults, more frequently in men than in women. Exposure, excessive venery, syphilis, trauma, infection, lead poisoning, etc., have been assigned as causes in individual cases. Some cases occurring near Rome, several of which were in one family, seemed to be due to the effects of a leguminous article of diet, *lathyrus cicera*. In quite a number of instances heredity was the chief factor in causation; the disease occurring distinctly as a family disease, having been found in a number of generations, with often a number of cases in the same generation. For instance, in one of Strümpell's cases the grandfather, father, two uncles, and a brother were supposed to have been similarly affected; in one of Spiller's cases fourteen, in five generations, were believed to have had the disease. In some of Strümpell's cases the disease appears to have begun in early, in others in late adult life. In Spiller's and a number of other reported cases it began in early childhood. In most of these cases the disease appears to have been very slow in its progress.

Symptoms.—The disease begins with weakness in one or both lower extremities. There is an undue sense of fatigue on exertion, and an objective examination shows a slight paresis. There is at the same time some difficulty in walking, this being at first most noticeable on rising in the morning. As the paresis increases, motor irritation symptoms are soon manifested. These are at first slight clonic or tonic spasms of the affected muscles. They are most likely to occur when the patient is fatigued, are easily evoked by active or passive movements of the limbs, but often come on in the middle of the night. The tendency to muscular spasm—brought on by either a voluntary or a passive movement, or in a reflex way—increases to such an extent that complete muscular rigidity and contractures of the limbs occur. This condition antagonizes every action of the patient, makes his voluntary efforts altogether futile, and, therefore, causes the paralysis to appear more complete than it really is. The rigidity can usually be overcome, in early stages of the disease, by slow persistent pressure, but when it becomes excessive it resists powerful efforts. The usual position of the rigidly contracted limbs is that of extension at the knees, the feet in the equino-varus position, and the thighs firmly pressing against one another. Their immobility is often interrupted by clonic spasms. Occasionally the limb is drawn for a short time into another position.

A striking and usually an early symptom is the exaggeration of the deep reflexes. The patellar tendon reflex is greatly exaggerated; muscular contractions can be elicited by striking any of the tendons—for instance, the inner or outer hamstrings, where tendon reflexes cannot be elicited, as a rule, in health,—and even tapping over the periosteum will produce like manifestations. But the most striking of these phenomena is the ankle clonus, rapid and rhythmical clonic contractions taking place when the foot is sharply flexed, and continuing as long as the foot is held in a flexed position. When the reflexes are much exaggerated the clonic contractions, on evoking the ankle clonus, may not be limited to the ankle, but may extend to all the muscles of the extremity. The ankle clonus also becomes a disturbing element in walking, as every time the body rests on the toes in progressing forward there is a tendency to its production. The most notable change in the superficial reflexes is the presence of the Babinsky toe phenomenon.

The gait is very characteristic. As the legs are weak and stiff the feet cannot be freely lifted, and, when moving forward, they sweep the floor, making an almost characteristic scraping sound. At the same time, in order that the foot can be brought forward, it makes a wide outward sweep. The gait is sometimes further impaired by clonic spasms of the muscles—those representing the foot clonus, as just described—and these spasms may cause a temporary halt in walking, or may make that act altogether impossible. Walking is more difficult on an up or down grade, and on an uneven surface, than on the level and on an even surface. It usually becomes easier after the patient has walked for a while. The gait just described is that observed when the spastic symptoms are already well marked. At a later period, when there is complete rigidity of the legs, walking is impossible.

The disease slowly extends upward, involving the muscles of the abdomen, back, and upper extremities. The latter are usually affected to a less degree than the lower extremities, though exaggerated reflexes and muscular tension are associated with the paresis. The upper extremities may even be rigidly contracted, in which case the position is usually one of slight flexion and pronation of the fore-arm, and strong flexion of the wrists and fingers, the arm being pressed firmly against the body.

In typical cases there are no further symptoms on the part of the nervous system. The sensibility is intact, the functions of the bladder and rectum are normal, there are no trophic changes in muscles or skin, and no special changes in the electrical reactions.

The progress of the disease is usually very slow. Though the patient be altogether bedridden and without power of motion, the general health need not suffer. Unless there be some complication he may live to old age.

The symptoms of spastic spinal paralysis are found in Little's disease, a congenital paralysis usually due to disease which has developed during fœtal life, or which is the result of injury to the brain in parturition. The brain disease, in these cases, is usually shown by such conditions as strabismus, speech disturbances, idiocy or imbecility, epilepsy, and the like. But in some instances there are no cerebral symptoms; the disease appears to be purely spinal and, therefore, belongs to this category. The pathological state, however, is likely to be due to a developmental defect. A definite determination of this question must await future pathological findings. Improvement in such cases is not uncommon.

The following case, at present under the writer's observation, illustrates this class of cases: I. J——, a boy eleven years of age, did not learn to walk as other children. Prior to that time nothing abnormal was detected. The spastic condition is now very marked. As he stands he rests altogether on his toes—the heels cannot be brought to the ground—and the thighs are pressed firmly together. When he tries to walk, which he can do only if well supported, the thighs rub each other and the legs cross. When the patient sits the feet and lower legs sway in the air. The rigidity of the limbs is such that much force is necessary to make any passive movements. The Babinsky phenomenon is present, and all the deep reflexes are exaggerated The ankle clonus, as well as those of the Achilles and patellar tendons, can be elicited. The intellect, sensation, and the functions of the bladder and rectum are unimpaired, and there is no evidence of the involvement of the upper extremities or of the cranial nerves. The disease, therefore, appears to be limited to the motor tracts of the cord.

Morbid Anatomy and Physiology.—Symptoms like those of spastic paralysis had been observed in connection with various diseases, but Erb was the first to describe this as a separate and distinct disease, whose basis he believed to be a primary sclerosis of the antero-lateral columns, especially the pyramidal tracts. His views have been quite generally accepted, but yet, it must be acknowledged, there has not been much positive evidence to substantiate them. In a number of post-mortem examinations, where this disease was diagnosed during life, lesions in the brain, tumors in the medulla oblongata, diffuse sclerosis, etc., were found. In some instances, nevertheless, the disease appeared to be a primary sclerosis of the lateral columns. But, whether or not a primary disease be usually found, it is probable that the pathological changes in the lateral columns produce the symptoms of this disease, for when spastic symptoms are found with multiple sclerosis, diffuse myelitis, etc., the lateral columns are found to be affected.

The paresis or paralysis is explained by the destruction of nerve fibres in the pyramidal tracts, the tracts conveying voluntary motor impulses. The motor irritation symptoms cannot be so satisfactorily explained. Charcot believed them to be due to dynamic changes in the large ganglion cells, these being placed in a state of irritation by the degenerated nerve fibres of the pyramidal tracts. Hughlings Jackson supposed that in these cases the influence of inhibiting centres in the brain had been removed by the destruction of the pyramidal tracts, and that the excessive motor manifestations were due to the absence of this influence.

Diagnosis.—The symptoms of spastic paralysis may appear with multiple sclerosis, transverse or diffuse myelitis, brain lesions, etc. In order to establish the diagnosis in these cases we must look for the further symptoms of these various diseases, as, for example, the indications of involvement of the gray matter and posterior columns in transverse myelitis; optic atrophy, nystagmus, intention tremor in multiple sclerosis, etc.

Especially in multiple sclerosis there may for a long time be no other symptoms than those of spastic paralysis. For that reason, when the latter symptoms are present, one should always be on the watch for other symptoms, symptoms that may indicate the presence of another disease.

It is to be remembered that this disease is one of long duration, that post-mortem examinatio s have been made only many years after its inception. In those cases, therefore, in which other changes have been found than those in the lateral columns—in Gowers', Goll's, the cerebellar tracts, etc.—the primary disease may have been only in the lateral columns. At present we can only make a diagnosis of spastic spinal paralysis. We cannot be certain, during life, that the disease in the lateral columns is primary, or that it is altogether limited to that part of the cord.

Prognosis.—When uncomplicated the disease does not appear to shorten life. It is sometimes capable of improvement, and even cures have been reported.

Treatment.—The treatment applicable in these cases is that usually adopted in locomotor ataxia and other forms of chronic disease of the cord. Rest in bed for a number of weeks, especially when there seems to be an exacerbation of the disease, may produce amelioration of the symptoms. Hydrotherapy, electricity, massage, applications of the thermo-cautery along the spine, the administration of various drugs, are among the remedial measures that may be used. In the spinal form of Little's disease tenotomy and other orthopedic measures, together with rest, have sometimes produced good results.*

(*b*) Amyotrophic Lateral Sclerosis.—For both the description of the symptoms and knowledge of the anatomical character of this disease we are chiefly indebted to Charcot. Though somewhat akin to the disease just described, it presents striking differences both in its symptomatology and in its morbid anatomy. It occurs chiefly in persons of middle age, but has been observed in children.

Symptoms.—The disease usually begins with slowly progressing paralysis of the upper extremities, which is soon accompanied by atrophy and fibrillary contraction of the paralyzed muscles. Subsequently muscular rigidity and contractures occur, the arms assuming the position found in spastic paralysis, viz., partly flexed at the elbows and pressed against the body, forearms pronated, hands and fingers strongly flexed. These contractures may remain even when the muscles are almost completely atrophied. Usually, after the lapse of a number of months the lower extremities become involved. In them the manifestations are mostly like those of spastic paralysis—paralysis, exaggerated tendon reflexes, muscular rigidity, contractures,—while little or no atrophy of the muscles is observed. The electrical reactions are altered

* Since this article was written Mills and Spiller have reported to the American Neurological Association a case in which there appeared to be a primary sclerosis limited to one pyramidal tract. The pathological findings are also given in the report.

according to the degree of muscular atrophy. In the lower extremities there may be a mere quantitative change—diminution of electrical irritability—while in the upper extremities the alteration is usually more marked, and, when the muscular atrophy advances rapidly, as often occurs in the small muscles of the hand, the typical reaction of degeneration may be found.

At a still later period bulbar symptoms, those of glosso-labio laryngeal paralysis—atrophy of the lips and tongue, difficulty in deglutition, indistinct speech, respiratory disturbances—appear, and finally carry off the patient.

The symptoms do not always appear in the order described. Sometimes the disease begins in the lower extremities, extending thence to the arms, and finally to the cranial nerves. Sometimes the disease begins as a bulbar paralysis, though it need not, therefore, run a rapid course. The writer has at present under observation a case which began with bulbar symptoms two years ago, and now presents a typical picture of the disease. In this case the muscles supporting the head upon the trunk are, also, almost completely paralyzed.

The degree to which spastic symptoms, and to which muscular atrophy appear in both upper and lower extremities, is also quite variable, depending upon the part of the nervous system in which the morbid changes began, and upon the extent to which the gray and white nervous tissues are respectively affected.

The duration of the disease is usually from one to three years. The well-marked cases hitherto recorded terminated fatally. Death is generally caused by the bulbar symptoms.

Morbid Anatomy and Physiology.—The morbid changes are almost, if not altogether, limited to the motor central and peripheral nervous apparatus. There is sclerosis—atrophy of the nerve fibres and increase of the connective tissue—of the direct and crossed pyramidal tracts in the cord, often extending above the crossing of the pyramids in the medulla. In some instances the atrophy has been followed the whole length of the motor pathway to the central convolutions, and atrophied pyramidal cells have been found in the cortex of these convolutions. There is atrophy of the large ganglion cells of the anterior cornua, and of the cells of the nuclei of the affected cranial nerves. Certain of the cranial nerves, of the anterior roots of the spinal nerves, of the mixed nerves and of the muscles, are also found in various stages of atrophy.

As to the explanation of the symptoms, the muscular atrophy is due to the atrophy of the large ganglion cells, the bulbar symptoms to disease of the nuclei of the cranial nerves, the spastic phenomena to sclerosis of the pyramidal tracts. The preponderance of spastic or atrophic manifestations is due to preponderance of the morbid process in the white or gray matter respectively.

Diagnosis.—While the disease is still confined to the upper extremities it may be mistaken for subacute poliomyelitis anterior, or even for progressive muscular atrophy, for the weakness, fibrillary tremor, and other manifestations—atrophied thenar and hypothenar eminences, claw-hand, etc.—are very much like what is observed in the latter disease. But its progress, even when unusually slow, is more rapid than that of progressive muscular atrophy. Furthermore, spastic symptoms, exaggerated tendon reflexes, some muscular rigidity, etc., are likely to be manifest at an early period, thus aiding us to distinguish it from the aforementioned diseases.

When the disease begins in the lower extremities or as a bulbar paralysis, it is as yet impossible to make a diagnosis of amyotrophic lateral sclerosis. At times in the bulbar form, spastic phenomena—the jaw clonus—are found. When the disease has developed in its typical form, with atrophic paralysis in the upper and spastic paralysis in the lower extremities, as well as with bulbar symptoms, no mistake is possible.

Myelitis, multiple sclerosis, gliosis, syphilis, may be so localized as to simulate this disease. But usually other symptoms—sensory and trophic symptoms and symptoms on the part of the bladder and rectum—will appear and thus differentiate these diseases from amyotrophic lateral sclerosis, which has only motor symptoms.

The prognosis is sufficiently indicated in the foregoing description. Such treatment may be resorted to as is employed in other chronic diseases of the cord.

Philip Zenner.

SPINAL-CORD DISEASES: MENINGEAL HEMORRHAGE.—Spinal hemorrhage is of two varieties: extrameningeal, between the dura mater and the bones; and intrameningeal. The last named may occur between the dura and the arachnoid, or between the latter membrane and the pia mater. The extrameningeal variety is the commoner.

Etiology.—Both on this score and on that of symptomatology a good deal of error appears to have been perpetuated by writers of text-books. The explanation of this fact lies in the relative infrequency with which the disease in question occurs. Hence writers are compelled to formulate their opinions on theoretical grounds rather than on actual observation in the clinic and in the pathological laboratory. The causative importance of spinal injuries seems particularly to be overestimated. In the writer's experience traumatic hemorrhage, either within or without the spinal envelopes, of sufficient extent to produce definite symptoms, is almost too rare—even in severe spinal fractures and fracture dislocations—to demand serious consideration. In the minor spinal injuries the symptoms attributed by many writers to meningeal hemorrhage could be attributed more logically to the pinching of nerve roots or to the transitory pressure on the cord resulting from the spinal distortion produced by the injury.

Meningeal hemorrhage occurs at all ages and is more common in men than in women. In early childhood it is never spontaneous; it merely gravitates into the spinal membranes from those of the brain, as in the case of the birth palsies. It is sometimes found post mortem in severe convulsive conditions, epilepsy, chorea, tetanus, puerperal eclampsia, and strychnine poisoning. It is also found in the hemorrhagic forms of certain acute specific diseases, such as smallpox and yellow fever; rarely as an isolated phenomenon in typhoid fever. In most of these cases it is probably an agonal phenomenon and is not recognized at the time of its occurrence. Extradural hemorrhage is a rare result of the bursting of an aortic aneurism, after erosion of the bodies of the vertebræ. Within the dura hemorrhage may result from the rupture of an aneurism of the vertebral artery.

Pathologic Anatomy.—Extradural hemorrhage is usually small in amount; it comes from the venous network which lies between the dura and the bone and is found mainly posteriorly, this situation being favored by gravitation and by the fact that the space between the dura and the bone is greater posteriorly than anteriorly. In very large effusions the blood may make its way out between the intervertebral foramina, along the nerves. The cervical region forms the commonest site for this variety of hemorrhage, and the blood is usually found more or less coagulated.

In making a post-mortem examination care should be taken, as Gowers has pointed out, not to fall into the error of considering as ante-mortem hemorrhage the blood which has gravitated into the meningeal veins and is subsequently released into the retrodural space when the canal is opened.

Intrameningeal hemorrhage varies greatly in amount. In the subarachnoid form it comes usually from the pial vessels and may surround the cord for a short distance, or fill the whole subarachnoid cavity. It has even been known to force its way through the valve of Vieussens into the cerebral ventricles. The cerebro-spinal fluid is often blood stained, a fact which may lead the observer into thinking the hemorrhage larger than it really is. In cases more than a few days old there are usually signs of meningitis, set up by the irritation of the effused blood.

Symptoms.—To produce any symptoms whatsoever the hemorrhage must be extensive. Such symptoms are at first irritative and result mainly from the more or less complete asphyxiation of the nerves which pass through the hemorrhagic area. The first indication is, as a rule, sudden with severe pain in the back. This pain is most intense at a point corresponding to the site of the hemorrhage, but radiates up and down the spine. With this pain in the back are others of a paroxysmal character, due to the irritation of the spinal nerves involved in the hemorrhage. These vary in distribution with the level of the cord implicated. Between the paroxysms of pain all sorts of disagreeable sensations may be experienced in the regions supplied by these nerves, the result of perverted function. More or less muscular spasm usually accompanies the pain; this may affect the vertebral muscles only so far as to cause rigidity of the spine, or it may produce actual opisthotonos; for the rest, it involves in part the muscles supplied by the affected nerves, and in part the muscles supplied by the cord below the hemorrhagic focus. There is usually spasmodic retention of urine. In a short time more or less paralysis follows this stage, but there is rarely if ever a condition of complete paraplegia. As a rule the sensorium remains clear throughout; occasionally unconsciousness may develop as a result of shock, and coma or delirium may come on.

Diagnosis.—Hemorrhage into the membranes, if at all severe, is usually marked by the group of symptoms above mentioned: sudden intense pain in the back, with spasmodic pain and other phenomena indicative of perverted function in the region supplied by nerves implicated in the hemorrhagic focus, muscular spasm followed by partial paralysis, spasmodic retention of urine, etc. In hemorrhage into the substance of the cord the pain is very much less in degree and more distinctly local, the paralysis is immediate, much more extensive and persistent, and the resulting atrophy more pronounced; the sphincteric disturbance is very marked and priapism is often present; the reflexes are abolished if the hemorrhage involves the entire transverse area of the cord, and increased if the lateral columns are mainly implicated. Should the cord hemorrhage make its way into the membranes the symptoms of both lesions will be combined, but even then the chronological order of the symptoms will enable one to follow the course of events. Meningitis has a more gradual onset, and fever is present from the outset; meningitis may, however, be started up by a hemorrhage, a fact that should be borne in mind. In myelitis the pain is very rarely prominent and the irritative phenomena so common to hemorrhage are *nil* or nearly so. Tetanus is differentiated by its more gradual onset, the presence of trismus and the absence of the severe spinal pains.

Prognosis.—In stormy cases the symptoms may reach their maximum in a few hours and death may result. This is particularly true if the cervical region is the one affected, owing to the implication of the phrenic nerves. If the patient survives the shock and exhaustion which accompany the culmination of symptoms, very gradual improvement may take place, with ultimate complete recovery. The danger is that the decline of the hemorrhagic symptoms may be followed, after a few days, by the onset of those of a meningitis which may prove fatal. If, however, the meningitis be of only moderate severity, it will begin to abate at the end of a week or ten days and gradual improvement will follow; complete recovery is a matter of many months.

Treatment.—Absolute rest is a prime requisite. The patient should be laid upon an air or water mattress and made to lie upon the face or side as much as possible, in order to have the spine elevated. The bladder and rectum should receive careful attention. Early scarification beside the spine, with free letting of blood, is a logical procedure, if the anatomical connection between the venous plexuses and the veins in the postvertebral tissues be considered. This may be followed by the application of ice to the spine and the internal administration of some form of ergot. The pain should be controlled by morphine or other sedative. If acute meningitis follows the hemorrhage, the treatment for this condition elsewhere indicated should be followed. The resultant paralyses are best dealt with by electricity and massage.

Surgical interference has been advocated by many in cases in which the early symptoms progress rapidly and the patient's strength remains good. The writer's experience with spinal surgery does not lead him to a warm advocacy of this measure. *Joseph W. Courtney.*

SPINAL-CORD DISEASES: MYELITIS.—Etiology.—Myelitis is one of the rarer forms of disease of the spinal cord. With the exception of certain special varieties, it is usually a disease of early adult life, and grows more infrequent in middle life and old age. The male sex seems to be much more predisposed than the female. Thus, among thirty-three cases under my observation there were twenty males and thirteen females. This discrepancy is probably owing to the greater frequency of the exciting causes among males.

The exciting causes of myelitis are numerous. The most frequent one, in the writer's experience, has been exposure to cold and wet. The disease is observed not infrequently after a debauch, if the patient has been compelled to sleep on the damp ground or lie in the gutter, etc. It may also result from working in ditches, or even from a brief exposure to wet and cold.

Traumatism plays a much less considerable part in the etiology of this disease. The inj y may be inflicted directly upon the spinal cord, as the result of gunshot and stab wounds, direct blows on the back, or even blows on the head. Injury to adjacent parts may also lead to myelitis. For example, in one of the writer's cases an injury to the back gave rise to a myositis in the erector spinæ muscle, attended with suppuration. After a long interval the pus made its way along the roots of the spinal nerves, through the intervertebral foramina, to the pia mater, where it set up an acute meningitis, and then extended to the substance of the cord, setting up myelitis. A certain amount of myelitis always attends spinal meningitis, but it is usually confined to the outer segment of the cord, and does not produce any notable symptoms.

Myelitis is also a frequent result of injuries to the spine (fractures, dislocations, etc.) which are attended with direct pressure on the cord; or it may occur in spinal concussion, when there is no evidence of injury to the external parts. In the latter form, however, the myelitis is more apt to be subacute or chronic.

Crocq reports a case of acute myelitis resulting from forced extension of the cord. So-called compression myelitis is also observed quite often, usually as the result of Pott's disease, more rarely of cancer or other tumors of the vertebræ. In the majority of cases, however, evidences of inflammation of the cord are wanting in this condition and the post-mortem appearances indicate degeneration due to interference with circulation. In some cases, however, evidences of myelitis are manifest.

In a considerable proportion of cases myelitis follows an infectious disease, being due either to the presence of bacteria in the cord or more frequently to the action of toxins circulating in the blood. Thus, cases have been reported after diphtheria, dysentery, typhoid fever, influenza, gonorrhœa, smallpox, measles. Schiff reports a case of acute hemorrhagic myelitis during the course of typhoid fever in which a fatal termination occurred eighteen hours after the onset of the spinal symptoms.

Among the rarer infectious sources of myelitis may be mentioned erysipelas, malaria, pneumonia, whooping-cough, scarlatina, puerperal sepsis, and streptococcus infection. Quite a number of cases have been reported in which a bronchiectatic cavity has been the starting-point of infection. Flatau reports a case which began several weeks after a suppuration of the antrum of Highmore.

Marinesco believes that the poison acts indirectly through the blood-vessels or directly upon the nerve tissues.

Moltschanoff found, upon injecting guinea pigs and white mice with gonococci toxins, that symptoms developed on the part of the nervous system, and marked changes in the cord were discovered on microscopic examination (colossal vacuolization of all the cells of the anterior and posterior horns).

It has also been claimed that myelitis may be due to tuberculosis or syphilis independently of local specific lesions.

Not a few cases have been reported as the result of acute or chronic poisoning with lead, arsenic, alcohol, or coal gas.

Formerly it was supposed that myelitis was not infrequently secondary to a cystitis or to inflammation of other parts of the urinary tract, the intervening link consisting of an ascending neuritis. At the present time we are inclined to believe that such cases are due to infection with the toxins of gonococci or streptococci.

In this connection we may mention an interesting case, reported by Dupré and Delamare, of a man, aged twenty years, with scoliosis of the dorsal spine since childhood. For ten years he had had a tuberculous process in the left upper maxilla and this was finally curetted. Two months later an apoplectiform paraplegia developed, with pronounced disturbances of tactile and thermal sensation in the legs. Atrophy of the muscles set in, with extensive bedsores and interference with micturition. After a short illness the patient died in a delirious condition. The diagnosis was tuberculous spondylitis and compression of the lumbo-dorsal cord. At the autopsy the spine was found to be intact, but there was extensive hemorrhagic pachymeningitis which encircled the lower dorsal cord like a thick ring. There were also secondary myelitic changes in various segments of the dorsal and lumbar cord. The microscope showed various stages of tuberculous inflammation of the dura. In the cord were found scattered islets in which the parenchyma and glia exhibited extensive degeneration, and there were irregular hypertrophy, with deformity of the posterior horns, and proliferation of the epithelial cells of the ependyma of the central canal.

Finally, in a considerable proportion of cases, we are unable to discover any adequate cause for the development of the disease.

Myelitis may be divided into several varieties, viz.: (1) *Transverse myelitis*, in which the entire thickness of the cord is affected, while the longitudinal involvement is slight, compared to the entire length of the cord; (2) *disseminated myelitis*, in which numerous small foci are scattered irregularly through the cord (this form is very apt to be complicated with a similar condition of the brain, really constituting an encephalo-myelitis); (3) *compression myelitis*; (4) *poliomyelitis*, in which the gray matter is the chief site of the lesion (this will be discussed in a separate article); (5) *purulent myelitis*, in which the disease terminates in the production of abscesses; (6) *chronic myelitis*.

Clinical History.—*Acute transverse myelitis* is rarely preceded by prodromal manifestations, unless this term be applied to the first symptoms of the beginning inflammation. In rare cases there is a feeling of general malaise, slight shivering sensations, or a distinct chill, and there may even be a certain degree of mild delirium; even general convulsions have been observed at the onset of acute dorsal myelitis, and still more often in cervical myelitis. Marked febrile movement is not often noticeable, however acute the inflammation may be.

The onset varies considerably in its degree of suddenness. In rare cases the disease begins as quickly as an attack of cerebral apoplexy. The patient suddenly feels a sense of weight in his lower limbs, this increases, and at the end of a few minutes the limbs are paralyzed. Or the onset extends over a week or more. At first a feeling of numbness, or of pins and needles, is noticed in the soles of the feet; this gradually spreads up the limbs, accompanied by increasing weakness of the parts, perhaps by severe pains in the muscles, particularly the calves of the legs, or by painful spasms of the muscles. Then the anæsthesia and motor paralysis continue to increase, sometimes uninterruptedly, sometimes by fits and starts, until they have attained their greatest intensity. The paralysis may be so complete that the patient is unable to move even the toes to the slightest extent.

Pain in the spinal column is not a pronounced symptom, nor do the patients, as a rule, complain much of tenderness in this region. The pains in the paralyzed muscles, sometimes in the joints, are extremely violent in certain cases, so that I have even known this condition to be mistaken for acute articular rheumatism. These pains may continue during the entire acute stage of the disease. A more constant symptom is the cincture feeling, a term applied to a painful sense of constriction around the abdomen, or thorax, varying according to the site of the disease in the spinal cord; this is usually attended with circumscribed tenderness over the corresponding portion of the spine. The cincture feeling is sometimes described by the patients as confined within very narrow limits, like those of a cord or thin ribbon; sometimes it is as broad as the hand.

In the majority of cases the pains in the limbs disappear as the paralysis becomes more pronounced, but in some instances they persist, even despite complete motor and sensory paralysis (anæsthesia dolorosa). When the pains in the limbs are severe they are usually attended with spasm or contracture of the affected muscles.

The bladder and bowels, especially the former, are usually implicated at an early period. The patient first experiences difficulty in passing water and must strain a good deal to start the flow. Finally, the inability to urinate may become complete, and the use of the catheter is necessary. Or the sphincter also becomes paralyzed, and incontinence results from overflow. The bowels are affected in a similar way, though less frequently. At first there is constipation, sometimes attended with extreme tympanites, from paralysis of the muscular coat of the bowels. Or the stools may pass away involuntarily, and, if anæsthesia is profound, this occurs without the patient's knowledge. In many cases, however, the functions of the bowels are quite undisturbed throughout the entire course of the disease. Even when voluntary evacuations are completely lost, the action of the bowels may sometimes be stimulated by reflex means, as by the passage of a catheter into the bladder, the irritation of the perineum, etc.

The cutaneous and tendon reflexes vary according to the exact site of the disease. Trophic symptoms are not an important feature in myelitis, apart from the atrophy of muscles seen in inflammation of the anterior horns of the cervical and lumbar enlargements. They are observed most frequently in the integument. Vesicular eruptions sometimes appear upon the paralyzed parts, and there may also be excessive desquamation of the outer layers of the skin. The formation of bedsores, which sometimes occur at such an early period as to indicate their trophic origin, will be considered later. We may also call attention to the fact that the changes in the urine, which are so common in this disease, are regarded by some writers as the result of trophic changes in the secreting structures of the kidneys.

Enlargement and tenderness of the knee-joints, sometimes attended with distinct effusion, occur rarely, and their interpretation is obscure. I have also found a similar "rheumatoid" condition in the ankle-joints in a few cases of myelitis.

Gowers reports a remarkable case of trophic disturbance in a patient suffering from subacute myelitis, in which the myelitic symptoms were complicated by cellulitis of the lower part of the abdomen. At the autopsy no local cause of the cellulitis could be discovered.

Vaso-motor symptoms are more frequent than the trophic changes, but possess little clinical importance. The temperature of the paralyzed parts is often changed. At first it is sometimes increased, but later, as a rule, it is decidedly lower than that of other parts of the body. Pitting of the limbs from slight subcutaneous œdema is also not infrequent.

The disease may be arrested at any period during its course, and may then terminate slowly in complete recovery. This is possible even after all the limbs are completely paralyzed, and after extreme wasting of muscles has taken place. As a general thing, however, recovery is incomplete. In the majority of cases the disease advances to a certain point, at which point it remains at a standstill, in some instances for a period of several years. In some of these cases further improvement is possible even after a long interval, during which the patient has remained *in statu quo*. Usually, however, the non-fatal cases terminate in the condition known as spastic paraplegia. The lower limbs gradually become more and more rigid, until finally each limb is moved as if it were one solid body. The feet cannot be flexed, the toes are shuffled across the floor, and the pelvis must be raised farther from the ground, in order to prevent the toes from catching in the floor. The limbs offer a decided resistance to passive motion. The tendon reflexes are often enormously increased. Ankle clonus often develops involuntarily if the patient, while sitting down, happens to bear his weight on the front part of the foot.

In much rarer cases the limbs become contractured in flexion, the thighs upon the abdomen, the legs on the thighs, the feet on the legs. At the same time the thighs are usually adducted strongly upon one another, so that one thigh is drawn forcibly across the other. In these cases bedsores are very apt to develop at the points at which the limbs come constantly in contact with one another. The patients very often suffer from intense pains in the contractured limbs, especially when an attempt is made to overcome the contracture. At other times the pains come on spontaneously in violent paroxysms, which are usually very difficult to control.

Death occurs generally from extension of the inflammation upward, and implication of the muscles of respiration; from gradual exhaustion, resulting usually from the formation of bedsores; or from disease of the kidneys consequent upon cystitis following paralysis of the bladder.

Bedsores develop over the sacrum, and are caused not alone by the protracted pressure on this part of the body, but also by soiling from urine and fæces, which is prevented with difficulty in many cases. In certain severe cases of inflammation of the lumbar enlargement bedsores may occur at a very early period, and then seem to be due directly to trophic changes in the skin.

With proper care and treatment the bedsores may remain confined to the integument, but not infrequently they extend more deeply, spread to the bones, and give rise to pyæmia; or, as I have also seen, the inflammation extends through the sacral foramina and sets up a rapidly fatal meningitis.

The occurrence of cystitis is also an important symptom. Perhaps in the majority of cases it results from the introduction of foul catheters, but it may also develop when such a cause cannot be discovered. The danger, in this condition, consists in the secondary development of acute interstitial nephritis, as the result of the introduction of bacteria along the ureter from the decomposing urine in the bladder. This complication usually proves rapidly fatal, but the writer has seen a few cases in which the post-mortem appearances warranted the belief that this morbid condition in the kidneys may subside. In such cases, however, death was the result of another attack of the same kind. But, on the whole, the renal affection seems to be a rare cause of death, even if the cystitis remains unchanged for a long time.

Close study of the symptoms enables us to localize the lesion very accurately in cases of transverse myelitis.

In myelitis of the lower part of the lumbar enlargement the motor paralysis is confined to the muscles supplied by the sciatics (gluteal region, posterior thigh group, and all the leg muscles, with the exception of the tibialis anticus). The sensory disturbances (complete or incomplete anæsthesia) extend over the entire lower limbs, with the exception of the parts supplied by the obturator and crural nerves (anterior and inner portion of thigh). Reflex movements in the paralyzed parts are abolished. The sphincter ani is paralyzed. When the lesion is a severe one the paralyzed muscles undergo atrophy, and the reaction of degeneration is observed.

In a lesion of the upper part of the lumbar enlargement the motor and sensory paralysis involves the lower limbs completely.

In a lesion of the dorsal cord more or less complete motor and sensory paralysis is observed in the lower limbs throughout, the anæsthesia extending upward to the intercostal nerves given off at the site of the lesion. The bladder and rectum are paralyzed. The muscles undergo very little or no atrophy, and the electrical reactions are unchanged. The cutaneous and tendon reflexes are increased on account of the abolition of the inhibitory influence from the brain.

In a complete transverse lesion of the cervical cord the paralysis affects all the limbs; when the transverse lesion does not cut across the entire cord the paralysis may be confined to the upper limbs (cervical paraplegia). The muscles of the trunk are also involved in these cases, and this process is a great source of danger to life on account of the resulting interference with respiration. In lesions of the lower part of the cervical enlargement the intercostals are paralyzed. If the lesion extends higher the diaphragm also becomes paralyzed, from implication of the nucleus of the phrenic nerves. As a general thing the muscles do not undergo atrophy, because the disease usually proves rapidly fatal. When the cilio-spinal centre is involved we may observe dilatation or contraction of the pupil, according as the centre in question is irritated or paralyzed.

Optic neuritis has also been observed in rare cases of myelitis of other parts of the cord (usually of the disseminated variety), but its relation to the spinal inflammation is not clear. The neuritis and myelitis probably are effects of the same underlying cause.

In lesions of the upper cervical cord the symptoms are similar to those just described; but in these cases the disease is apt to spread into the medulla oblongata, and to involve certain of the cerebral nerves. The following brief abstract will illustrate the history of acute myelitis of the upper cervical cord, extending into the medulla oblongata.

A. B—— contracted syphilis two months ago. At the present time he exhibits a roseola, and is suffering from slight sore throat. On November 12th he had sexual intercourse while standing. During the same night he complained of an uneasy feeling in the legs, and of slight numbness in the tips of both middle fingers and in the feet. On the next day he walked up five flights of stairs twice; then the legs began to feel heavy. He managed to get about his room on the following day (Saturday), but on Sunday morning was unable to rise from bed. At my first visit (November 16th, 6 P.M.) I found the patient in the following condition: Almost complete paralysis of the lower limbs; slight motion of the thighs; a little reflex action from the soles; numbness of the entire limbs. He could hold his water, but after it began to flow he was unable to check it. There was very marked paralysis of the upper limbs, especially the right limb, but most movements could be performed slowly; partial anæsthesia of the upper limbs and trunk, none of the face; voice a trifle hoarse; temperature, normal; respirations, 16; pulse, 84 and of good quality. The patient does not use the diaphragm in breathing, but can do so quite well voluntarily. He says that he sometimes has difficulty in breathing, and cannot cough as well as yesterday.

November 17th, 9 A.M.—Passed a bad night, unable to sleep at all; whenever he was about to doze off he had to struggle for breath; had one bad attack of dyspnœa which lasted three hours. No reflex from the soles of the feet; power absolutely lost in lower limbs; also worse in upper limbs, particularly the right; sensation more blunted; passed a large quantity of urine at 5 A.M.

Respiration, 20; pulse, 90; respirations interrupted occasionally by a long breath; more difficulty in breathing; still moves the diaphragm voluntarily, but not so vigorously as last night. Speech is more hoarse, the vowels are not enunciated very clearly. Slight anæsthesia of the left side of the face, paresis of the left internal rectus, also of the right side of the face. He has double vision over a small area a little to the left of the median line on the horizontal. All the right facial muscles are paretic; he is unable to close the right eye entirely.

November 17th, 8 P.M.—Condition unchanged, has slept at intervals, once for half an hour at a stretch.

November 18th, 10 A.M.—Left pupil slightly dilated, but reacts to light; left side of face not so numb; paresis of internal rectus improved; no double vision; enunciates vowels more distinctly. Paralysis of the limbs is a little more marked; no reflex from soles; urine passed freely. During the night had severe pain between the shoulders; respiration, 22; pulse, 86; diaphragm not so active, but respiration easy.

November 18th, 9 P.M.—Respiration, 33 and more labored; diaphragm weaker; pulse, 84 and weaker. Skin cool and covered with cold sweat; looks a little bluish; face flushed; patient seems excited and talks a good deal—says "he is off his nut because he has taken too much brandy"; pupils normal; speech more difficult, vowels less distinct; does not swallow so well. The patient died at five o'clock the following morning, after increasing difficulty in breathing.

Disseminated myelitis is almost always an infectious or toxic affection. In comparatively rare cases the lesions are confined to the cord, but in the majority of cases they are also found in the medulla, pons, and other parts of the brain. If the lesions in the cord are grouped in such a manner that the transverse section is involved in great part, the symptoms closely resemble those of transverse myelitis. In a considerable proportion of cases, however, an acute ataxia develops, frequently in all the limbs at the same time. The patellar reflexes, instead of being lost as they are in tabes dorsalis, may be exaggerated. The muscles exhibit loss of power, varying in degree from slight paresis to complete paralysis. The lightning pains of tabes are absent and the sphincters may be unaffected. Optic neuritis is not uncommon. When the medulla and pons Varolii are affected, as is generally the case, we may observe scanning speech, nystagmus, tremor, occasionally attacks of mental excitement, as in multiple sclerosis.

So-called *compression myelitis* is usually, as we have intimated in the section on etiology, not a real inflammation. But as this point can be decided only upon autopsy, and not by the clinical history, we will here give a brief description of this condition.

In the majority of cases compression myelitis is the result of Pott's disease and the lesion is situated in the dorsal region. The malady is often preceded by symptoms of irritation of the roots of the nerves by the diseased bone or the secondary pachymeningitis. These irritative symptoms consist of a cincture feeling around the abdomen or chest (according to the location of the vertebral lesion), or of pains in the legs; sometimes there is an eruption of herpes zoster upon the trunk or the lower limbs.

Weakness of the limbs generally begins slowly and finally advances, as a rule, to profound paralysis. This may be preceded for quite a while by marked exaggeration of the knee-jerk and ankle clonus. In the same way these symptoms may persist for a long time after the restoration of motor power.

After the motor paralysis has developed the symptoms differ in no respect from those of ordinary transverse myelitis, except that there is usually a much greater discrepancy between motor and sensory paralysis, the latter being very often entirely absent. The paralysis exhibits very little tendency to extend beyond the parts originally involved. In a certain proportion of cases the lower limbs become contractured—the thighs flexed on the abdomen, the legs on the thighs—or shooting pains in the lower limbs become a prominent feature of the disease. To judge from his own experience, the writer is inclined to believe that this condition is particularly apt to develop when the myelitis is the result of irritation of the cord rather than of compression by morbid products.

When the compression myelitis is the result of cancer of the vertebræ, pains in the lower limbs and trunk are extremely distressing, and, if cutaneous sensation is abolished at the same time, the condition is known as anæsthesia dolorosa. Apart from the excessive violence of the pains, this paraplegia dolorosa cannot be distinguished from other forms of compression myelitis.

Purulent Myelitis.—Purulent inflammation of the spinal cord is much rarer than the similar process in the brain. On account of the protected location of the cord, injuries to the latter and hence surgical infection are uncommon. On the other hand, purulent myelitis has been observed after injuries to the vertebræ without direct lesion of the cord. In such cases the infectious bacteria must have been conveyed through the lymph channels. The disease occurs most frequently as a sequel to suppurative meningitis. It is also possible that the pus-producing germs are conveyed to the cord and meninges at the same time. A few cases have been reported as the result of metastases in remote parts of the body: for example, after abscess of the lung, putrid bronchitis, suppurative processes in the genito-urinary tract, etc.

The symptoms of the disease are generally those of a transverse myelitis, associated perhaps with unusually pronounced meningitic symptoms and evidences of profound general infection. As a rule, the diagnosis of the suppurative character of the inflammation is not very difficult after recognition of the etiological factors in the case.

Chronic myelitis is a much rarer affection than the acute or subacute form of the disease. The causes of chronic myelitis are similar to those of the acute form. It is generally held that the difference in the mode of beginning is the result of differences in the intensity of the etiological factors—for example, sudden and violent exposure will produce acute myelitis, long-continued and less severe exposure will produce chronic myelitis;—but it seems to me that this view is based on theory rather than on well-established clinical facts. In traumatic cases a single traumatism may set up an acute myelitis or an inflammation of the cord which does not make its appearance until long after the symptoms of the original injury have subsided. Perhaps there has been some spinal pain for a few days or weeks after the injury, then the patient feels entirely well; but, a few months later, the signs of slowly advancing myelitis make their appearance.

Syphilis seems to exert a considerable influence as a predisposing cause, but it is questionable whether it acts simply by making the spinal tissues more vulnerable or by the production of gross lesions in the vessels or membranes of the cord. It seems probable, however, that in a large proportion of such cases the former theory is correct, the syphilitic virus appearing to act as a potent predisposing factor, as it does in the production of locomotor ataxia.

Alcoholism also appears to exercise great influence in the production of chronic myelitis; but we must bear in mind that this vice is often connected with repeated exposure to cold and wet, and to violence, and that it is difficult to decide between the parts played by each of these factors.

The *symptoms* of chronic myelitis are very similar to those of the acute form, except that they develop very slowly and insidiously. In some instances this gradual course may be interrupted occasionally by more or less acute exacerbations. In the majority of cases the disease affects the dorsal region, and hence the symptoms are those of slowly developing paraplegia. As in the acute form, the sensory symptoms are generally much less marked than the motor phenomena. The patient complains of formication and tingling in the feet, or of a sense of numbness in the soles, so that the floor does not feel natural in walking. This condition may last a very long time, although no change in sensation can be noticed objectively after the most careful examination. Pain is not a prominent feature, although there is often complaint of a slight girdle feeling around the abdomen. In a few cases, however, the pains are remarkable for their violence. Slight, dull pains are often felt in the back and limbs, particularly after walking for some length of time. These symptoms may last a long time before any motor weakness becomes apparent. The patient notices that he becomes more tired than usual after walking, and finally begins to drag the legs. Rigidity of the lower limbs is an early and almost constant accompaniment of the loss of power (spastic paraplegia). In many cases, indeed, I have noticed a marked development of this spastic condition before any real loss of power could be detected. At the same time the tendon reflexes are notably increased. In some cases disturbances of sensation, which can be determined by objective examination, may be entirely absent, and subjective sensory disturbances may also be extremely slight, or wanting. The symptoms are then exactly similar to those of so-called primary lateral sclerosis, and may remain in this stage for several years before the advent of other symptoms attests the spread of the disease.

In a very small proportion of cases, particularly in those which are due to syphilis, the lesion is confined to a small section of the cord, and, if limited to one-half, may give rise to the symptoms of spinal hemiplegia (paralysis of motion on one side, paralysis of sensation on the opposite side). As a general thing, however, the lesion is not confined exactly to one half of the cord, but extends somewhat into the other side, and motor and sensory symptoms are therefore observed in each limb, although the paralysis of motion is more marked in one limb, that of sensation in the other limb. In this form of the disease, sensory symptoms (anæsthesia, pains in the back and limbs) usually form an important feature.

As a general thing, the lesion spreads slowly along the cord in an upward or downward direction (usually the former), and other parts of the body become involved. The spread of the disease may be exceedingly slow, and even twenty or thirty years may elapse before the final termination. In other cases the chronic course may be interrupted by acute exacerbations. I have also seen several cases in which the symptoms of chronic myelitis appeared to merge later into those of posterior sclerosis or multiple spinal sclerosis.

Spastic symptoms are apt to be extremely severe in this form of myelitis. In the most aggravated cases the muscles are contractured to such an extent that the thighs may be flexed sharply on the abdomen and the legs flexed firmly against the thighs. The rigidity may be so pronounced that the entire body is moved as a whole when the force is applied to the feet. We then find not infrequently that the pressure of one knee upon the other gives rise to the formation of bedsores, and these are also apt to develop upon the sacral and gluteal regions. With proper care and nursing the bedsores may often be prevented, but the absolute helplessness of the patient always entails great suffering. It is a surprising fact, however, that the patient often exhibits a cheerful frame of mind during the entire course of the disease.

In a considerable proportion of cases the functions of the bladder and bowels are notably impaired, but it is found not infrequently, even in the most spastic cases, that the patients still retain considerable power over these organs.

When the sensory disturbances (paræsthesiæ and pains) are severe, the condition of the patient is truly pitiable. Unfortunately, he may remain in this state for many years until finally an intercurrent affection brings relief in death.

In concluding the clinical history of myelitis I will refer briefly to a mode of termination which has been unnoticed by the majority of writers. In a number of cases which have come under my observation the disease appeared to begin as a transverse myelitis; but the symptoms cleared up, in great part, and then merged into those of locomotor ataxia. In the following case I was fortunate enough to obtain a post-mortem examination:

J. D——, thirty-five years of age, married; entered Randall's Island Hospital on September 4th, 1883. The patient gives no evidence of syphilis; habits regular.

The present illness has lasted nine months; it began with ptosis of the right eye; shortly afterward he began to have shooting pains in the legs and arms. In a few weeks he had to quit work on account of the pains and weakness in the lower limbs. About five months ago the patient became so weak that he was unable to walk, and had trouble in holding his water.

Present condition (October 4th, 1883).—Patient walks with assistance, but has a characteristic heel gait, and must watch the movements of his feet; he reels to and fro when standing with the eyes closed.

Anæsthesia and analgesia are present, below Scarpa's triangle, in both thighs and legs; patellar reflexes are absent. Slight inco-ordination of upper limbs, and some numbness of the fingers. Partial ptosis of right eye; both pupils very much dilated, and react poorly to light; optic papillæ unchanged; special senses normal. The dynamometer is forced to forty by the right hand, to thirty-six by the left hand.

October 24th.—Had a pulmonary hemorrhage; dulness and a few moist râles over the upper lobe of left lung.

The motor power of the lower limbs improved considerably, but the inco-ordination rapidly grew worse, the limbs jerking in every direction when any voluntary movement was attempted. There was very marked emaciation, but the muscular power finally appeared to be normal compared with the amount of muscular tissue retained. The ptosis disappeared almost entirely; sight remained normal. The phthisis continued to advance, and the patient died January 7th, 1885, without the development of any fresh symptoms on the part of the nervous system.

Microscopic examination of the spinal cord showed exquisite sclerosis of the posterior columns (enormous increase of the neuroglia and of nuclei), together with a general increase of connective-tissue elements in the remaining portions of the cord, with the exception of the gray matter, which seemed to be perfectly normal. In addition, the blood-vessels of the posterior columns were very much dilated, and their walls were exceedingly thickened, particularly the adventitia, in which the nuclei were enormously increased. The nuclei around the central canal were increased in number, and there seemed to be, also, an increase of fibrous tissue in this locality. Here and there in the other columns of the cord were seen blood-vessels which also presented a considerable increase of nuclei.

Pathological Anatomy.—In a good many cases of acute myelitis no change in the structure of the cord is visible to the naked eye. Sometimes the diseased parts are softened, and their color is changed. The cord cuts less firmly than in the normal state, the cut surface projects as if the cord were too large for the enveloping pia mater, and the normal differentiation between the white and the gray matter becomes less distinct or is completely lost. The entire surface has a reddish tinge; sharply defined reddish streaks (distended blood-vessels) are often seen, particularly in the white matter; and here and there we occasionally notice minute red specks (capillary hemorrhages). In some cases these hemorrhages form the most marked change recognizable by the naked eye, and the cut surface has a bright red, or, at a later stage, chocolate color (hemorrhagic myelitis). The degree of softening varies between very wide limits. In some cases it is entirely absent, in others it is so pronounced that the diseased part of the cord, but particularly the gray matter, is diffluent and flows out like cream.

Schmaus and Sacki give the following description of the pathological anatomy of the various forms of myelitis:

Transverse Myelitis.—In this form of the disease we may find one large focus or several smaller ones. These foci exhibit the appearance of parenchymatous degeneration with swelling, or pronounced vascular changes, or there may be softening, with or without hemorrhage.

In some places the white substance shows marked swelling of the axis cylinders and medullary sheaths; the latter may have a vesicular appearance and stain poorly with Weigert's solution. The swollen axis cylinders, on transverse section, form partly homogeneous, dark-stained bodies, or pale, finely granular bodies. Marchi's method of staining may show black coloration of the swollen fibres, indicating beginning fatty changes. Longitudinal sections show that the axis cylinders break up into smaller segments, and these pieces are often enclosed in swollen medullary substance; if the latter has undergone fatty degeneration, an appearance of granular corpuscles may be simulated. The neuroglia is also involved; the fine fibrillæ, which separate the individual nerve fibres, are swollen into thick, homogeneous bands, which often take a deeper stain; the glia cells are often swollen and enlarged. In addition, we find arterial hyperæmia, dilatation of the small arteries and veins, homogeneous or slightly granular masses of exudation in the interstitial tissue, masses of leucocytes in the walls of the vessels or free in the tissues, and more or less numerous granular corpuscles. When the gray matter is involved, the ganglion cells exhibit interesting changes. These begin with swelling of the granules capable of staining, or with a finely granular distribution of the tigroid substance. Next come changes in the cell body as a whole, viz., homogeneous swelling or degeneration of the cell and its processes, shrivelling of the cell, changes in pigmentation, vacuolar degeneration, finally complete disappearance of certain cells or groups of cells. The nuclei also exhibit signs of degeneration; they stain more deeply, grow smaller and darker, are irregular or fissured, and finally coalesce completely with the body of the cell.

In a second group of cases, the vascular changes are most prominent. The microscope shows that the chief change is a small-cell infiltration, most marked around the vessels and following them along their course. The cellular infiltration occurs chiefly in the lymph sheaths of the blood-vessels, but it also extends into surrounding parts and into the meshes of the neuroglia; sometimes even the pericellular spaces around the ganglion cells are filled with such small-cells. We also find hyperæmia and serous infiltration of the tissues, with secondary conditions of swelling. Not infrequently the evidences of degeneration of the nerve cells and fibres are found to extend diffusely over large areas, while the infiltration occurs only in scattered foci. In other cases, however, the swelling and degeneration are not alone less widespread than the cellular infiltration, but may even be confined to the foci of infiltration, while the remaining tissues are almost unchanged. Sometimes the nerve fibres and ganglion cells are well preserved, even within the zone of infiltration, and evidently are only affected at a late period of the disease. This indicates that the inflammatory process is first manifested in the walls of the vessels. More or less extensive hemorrhages not infrequently accompany the infiltrations. Granular corpuscles in the meshes of the neuroglia become more numerous the longer the process lasts. Even in cases which have lasted only a few weeks we sometimes find the walls of the blood-vessels thickened by cellular proliferations and the lumen diminished by thickening of the intima (endarteritis obliterans).

In a third group of cases the chief feature is a condition of softening, due to infiltration with granular corpuscles. The foci may have the consistence of porridge, or they may even be diffluent on section, leaving vacuolæ. The softening spots consist almost entirely of granular corpuscles, together with detritus of the nerve tissues. In sections which have been stained with Weigert's "medullary-sheath stain," the softened spots appear as brownish-yellow or colorless patches. The vessels show even more pronounced changes than in the previous group. Thrombi are found in some of the vessels, and these may be responsible for a part of the softening. There are also hemorrhagic forms of inflammatory softening; in the slightest grades capillary hemorrhages are found in the softened spots and surrounding parts, and give rise to a speckled appearance.

As a matter of course there are numerous transitions between the three forms just described. A transverse lesion is followed regularly by ascending and descending degenerations.

Acute Disseminated Myelitis.—In this form of disease the various foci exhibit a pronounced vascular character; small vessels form the centre, around which are grouped the swelling and degeneration of the tissues, as well as the infiltration with round cells and granular corpuscles. Larger foci involve several vessels, but even here we find distinct signs of vasculitis, viz., distention of the vessels with blood, small-cell infiltration of the walls of the perivascular and adventitial lymph sheaths, and deposit of granular corpuscles. In older cases there are not infrequently thickenings of the walls of the vessels, especially of the tunica intima. The infiltration with granular corpuscles may be so dense and the degeneration of the tissues so pronounced that the appearances of softening are produced; in other cases hemorrhages are present.

Purulent Myelitis.—Abscess of the cord is of rare occurrence. Infection-producers may enter the cord in three ways: after injury to the cord with direct infection from the outside, through the lymphatics, or through the blood-vessels. If the bacteria enter through the blood-vessels, they may be simply carried along by the current of blood or they may be conveyed in emboli. The latter give rise, in the nervous tissues, to suppurative softening. Apart from traumatic purulent myelitis, the disease is most frequent after suppurative spinal meningitis.

Chronic Myelitis.—Histologically the diseased parts of the cord exhibit either degeneration and sclerosis or a condition of softening, with or without degeneration and proliferation of the glia.

In the former event we find swelling and segmentation of the axis cylinders, fatty degeneration of the medullary sheaths, the formation of hyaline bodies and corpora amylacea. The disappearing parenchyma is replaced by proliferating neuroglia tissue. The blood-vessels present cellular infiltration of their walls (especially of the adventitia, but sometimes of the media and intima), thickening of the walls, adhesion and obliteration of their lymph sheaths, and often dilatation of the perivascular lymph spaces. In some cases there are no decided changes in the vascular apparatus, but the myelitic foci have peculiar relations to the vessels, inasmuch as we often find more or less changed vessels at the centre of the diseased foci, or tracts of degeneration follow the course of the vessels.

The second form of chronic myelitis is that of softening. It is difficult to decide whether the spots of softening are the result of an inflammatory process or of a simple disturbance of circulation. If the softening is owing to infectious or toxic causes, the process may continue as long as these causes are active. It must also be remembered that softening often causes disturbance of circulation in its vicinity, and that the neighboring parts are in a condition of more or less marked œdematous swelling. Hence the softening may continue even after the toxic or infectious agent has ceased action.

With regard to the secondary degenerations of the cord, which are found after myelitis, we refer to other articles in the present series.

Diagnosis.—Acute myelitis must be distinguished from meningitis. The latter affection is very much rarer than acute myelitis, apart from those cases in which it is associated with inflammation of the cerebral pia matter. In meningitis the pains in the back and limbs, the cramps in the muscles, and the hyperæsthesia, are much more marked than in myelitis, and usually persist for a much longer time. Paralytic symptoms are not pronounced, and the bladder and rectum, as a rule, are unaffected. In myelitis, on the other hand, the initial irritative symptoms are often entirely absent, or, in the very large majority of cases, soon give place to anæsthesia and motor paralysis. With the exception of certain cases of inflammation of the cervical cord, fever is usually absent or slight in myelitis; in meningitis there may be decided febrile movement.

In two cases I have seen acute myelitis mistaken for acute articular rheumatism—once in a child suffering from compression-myelitis dependent upon Pott's disease, another time in an adult with extremely acute dorsal myelitis. In both patients the joints of the lower limbs were very tender on pressure, and in the adult there was high fever. In the former, however, examination of the spine revealed a well-marked kyphosis, the loss of power was disproportionate to the apparent severity of the pain, and the tendon reflexes were greatly exaggerated. In the latter the patient also suffered from rapid pulmonary phthisis, which explained the high fever; the pains were not confined to the joints, but were also marked in the muscles, and the lower limbs were anæsthetic (anæsthesia dolorosa).

Hysteria is sometimes mistaken for myelitis, especially when it occurs in young females; or, *vice versa*, myelitis is sometimes, though less frequently, regarded as hysterical paraplegia. The occurrence of other undoubted evidences of hysteria is an important point in diagnosis; but too much stress should not be laid upon this feature, since it must be remembered that hysterical individuals are also liable to be attacked by myelitis. The etiology should also be taken into consideration, and, in the absence of any of the causes previously mentioned, the diagnosis of myelitis in a young female should be looked upon with suspicion. In hysterical cases, however, the evidences of serious organic lesions of the cord are always wanting. There is no pronounced wasting of muscles, no change in their electrical excitability, no loss of power of the bladder and rectum. On careful observation, moreover, it is often found that the apparent paralysis varies in different positions of the body, and that there are sudden changes in motility which remain inexplicable on the theory of an organic disease of the cord.

The diagnosis from hemorrhage of the cord is usually easy, except in cases of hemorrhagic or apoplectiform myelitis, when the symptoms have come on with extreme rapidity. Hemorrhage into the spinal cord is extremely rare, except as the result of injury. The symptoms of motor paralysis attain their utmost severity at once, and then, unless the hemorrhage is situated high in the cervical region, begin to improve slowly up to a certain point. With the exception of the suddenness of the onset, and the previous occurrence of traumatism, there is really no means of differentiating spinal hemorrhage from acute myelitis. In the majority of cases, indeed, the hemorrhage is followed by myelitis, either as the result of the injury to the elements of the cord from the traumatism, or as the outcome of the irritation excited by the clot.

The diagnosis of acute disseminated myelitis is extremely difficult and often impossible. Great importance attaches to the etiology of the disease, as almost all the reported cases have followed traumatism or an infectious or toxic condition. When the process results in paraplegia a probable diagnosis can be made if ocular symptoms are marked, or if there is an early development of bulbar or cerebral symptoms (scanning speech, tremor, hallucinations, mental obtuseness, etc.). When the disease is manifested by an acute ataxia, an important diagnostic feature is the preservation or even exaggeration of the tendon reflexes. Like the paraplegic variety, the ataxic form is also attended by bulbar and cerebral symptoms.

In the majority of cases of compression myelitis the primary lesion is caries of the vertebræ, and, as a general thing, the deformity of the spine is so pronounced that there can be very little doubt with regard to the diagnosis. In Pott's paraplegia, moreover, the exaggeration of the cutaneous and tendon reflexes may precede other symptoms for a considerable period, and may persist after other evidences of myelitis have disappeared. In addition, the sensory symptoms are usually much less pronounced than those in the motor sphere, and may even be entirely absent, despite complete paralysis of the limbs. In a few cases, however, particularly when the patient has been confined to bed on account of some other disease, spinal deformity may not be noticed, and the myelitis is then apt to be regarded as primary.

When compression myelitis is secondary to cancer of the vertebræ, the recognition of the nature of the primary disease usually depends on the presence of a primary cancer in some other part of the body, on the violence of the pains in the paralyzed parts (especially if associated with anæsthesia), and on the presence of a deformity of the spine which seems to be due to an irregular enlargement of the vertebral arches or lateral masses. It must not be forgotten, however, that cancer of other parts of the body may be associated with ordinary vertebral caries. In a case of this kind recently under my observation, I made the diagnosis of compression myelitis from vertebral cancer, but the autopsy proved that the disease had been an ordinary Pott's paraplegia.

Diagnosis.—Railway spine, when due to chronic myelitis or meningomyelitis, may prove a source of great difficulty in diagnosis, especially because the element of malingering so often comes into play in this condition. When this factor can be excluded, the diagnosis is based on the slow development, at a variable period after the injury, of symptoms which point to disseminated focal lesions of the cord, viz., irregularly distributed paralyses, various paræsthesiæ, pain in the spine and limbs, disturbances of micturition, localized atrophies of muscles. A depressed and irritable condition of the mental faculties, with loss of memory, is quite common in this condition.

The diagnosis of chronic compression-myelitis is made in the same way as that of the acute form, except that the symptoms develop much more slowly. Acute exacerbations are particularly apt to develop in this form of the disease.

Chronic myelitis can be distinguished from the persistent paraplegia left over after an acute attack only by the history of the onset of the illness. When, for any reason, the patient is unable to furnish the previous history, the diagnosis is impossible.

Tumors of the spinal cord or its membranes are rare, and their differential diagnosis from chronic myelitis is extremely difficult. The clinical history of the former consists essentially of symptoms of irritation of the nerve roots, followed by those of compression of the cord. In some cases, however, the latter precede the former. The compression of the nerve roots sometimes lasts a long time before the evidences of compression of the cord make their appearance. Probably the most important point in the differential diagnosis is the great variation which is sometimes noticed in the severity of the symptoms. In addition, it is found not infrequently that the first evidences of compression of the cord occur in the form of spinal hemiplegia, owing to the fact that the tumor often develops first in one lateral half of the cord.

Chronic myelitis is not apt to be mistaken for hysterical paraplegia, because the latter disease begins much more abruptly than the former.

The diagnosis of the localization of the inflammation in the cord depends upon the grouping of symptoms, for which we refer the reader to the section on clinical history.

Prognosis.—Complete recovery from acute myelitis, with the exception of the compression-myelitis of Pott's disease, is a comparatively rare result. Incomplete recovery is by far the most frequent termination, although a fatal issue is by no means uncommon. Other things being equal, the disease is more apt to end fatally the higher the location of the lesion in the cord. If the centre for the phrenic nerve has been attacked, as shown by paralysis of the diaphragm, recovery is extremely rare. The occurrence of bedsores is likewise of grave import, particularly if they develop at an early period.

When they occur after the disease has lasted a long time, they often heal quite rapidly under suitable treatment. Mild cystitis is so common in myelitis that it can hardly be regarded as aggravating the prognosis; but in severe cases, especially if the bladder is completely paralyzed, there is always danger of the production of acute interstitial nephritis. The latter affection is almost inevitably fatal at an early period, though in some cases it seems to pass into a stage of quiescence.

The prognosis as regards recovery is also so much less favorable the greater the degree of implication of the gray matter, as evidenced by rapid atrophy of the paralyzed muscles and by the presence of the reaction of degeneration in these parts. But it must also be remembered that even the most marked atrophy of the muscles and complete abolition of their electrical irritability do not entirely preclude the possibility of a very satisfactory degree of recovery. I have had under observation a patient in whom the limbs were completely paralyzed and wasted to the extreme, and the reaction of degeneration was present except in those muscles in which no reaction could be obtained (even the intercostals were partly paralyzed); and yet this patient, at the end of a year and a half, was able to walk about and to perform her duties in such a satisfactory manner that she requested her discharge from the hospital.

The occurrence of a spastic condition of the lower limbs constitutes an almost insuperable obstacle to any further improvement. The degree of motor power which is acquired in these cases, however, is usually quite considerable, and the patients are often able to move about quite freely, unless the rigidity of the limbs is excessive.

Pott's paraplegia generally offers a favorable prognosis, unless the vertebral caries itself, or its sequelæ, constitute a serious menace to life. Improvement in apparently hopeless cases sometimes comes on quite suddenly, and the patient may recover even from a number of severe attacks. In these cases there is always danger of a relapse so long as the tendon reflexes remain exaggerated.

The prognosis of chronic myelitis is always grave. Even chronic compression myelitis, which, of the different forms of the disease, presents the most favorable outlook, rarely terminates in recovery. Unless the slow course of the spinal inflammation is interrupted by acute exacerbations, the patient may linger for years. The longest lease of life is enjoyed in those cases of transverse myelitis in which the disease does not extend up the cord. The greatest danger in these cases arises from the development of cystitis and secondary interstitial nephritis.

In the syphilitic forms of chronic myelitis we are sometimes able to secure a fair degree of recovery, especially if treatment is begun before the disease has extended across the entire section of the cord. But even here it will be found that complete recovery rarely takes place.

It is held by many writers that cases of railway spine, which is probably due to chronic myelitis and meningomyelitis, usually recover; but this statement does not agree with the experience of the majority of unbiassed observers.

Treatment.—The most important indication is to secure as absolute rest in bed as is possible under the circumstances. As soon as any symptoms which suggest the onset of myelitis make their appearance, the patient should take to bed and remain in the recumbent position. The wants of nature should be attended to with the aid of the bedpan, in order to avoid, as much as possible, movement during the acts of urination and defecation. Rest is, in my opinion, by far the most important remedial agent at our command. It is often difficult to determine at what period it is best to allow the patient to begin to exercise the paralyzed limbs, but it is always better to err on the safe side. I have seen very marked improvement in a number of apparently hopeless cases in which this plan had been faithfully carried out for a period of a year to a year and a half.

Contracture of the tendo Achillis is a very common sequel of all forms of myelitis, and it has been suggested that the pressure of the bedclothes upon the feet may exercise some influence in the production of this unfortunate symptom. In order to obviate this, the bedclothes may be suspended on a barrel hoop placed across the lower part of the bed. In a considerable number of cases, however, the contracture will develop despite this precaution.

Next to rest, cleanliness is all-important, because the neglect of cleanliness is very apt to result in the production of bedsores. This usually necessitates the most careful nursing. The external genitalia and gluteal regions must be frequently washed, and thoroughly but gently dried. At the slightest indication of the development of a bedsore, an air-ring should be placed under the buttocks, care being taken that the joints of the ring are not sharp. If the evidences of dermatitis are not relieved speedily in this way, the patient should be placed on a water-bed.

The bladder must be carefully looked after. Catheterization must be resorted to at once, as soon as the bladder is no longer thoroughly emptied. The greatest precautions must be taken to keep the catheter thoroughly aseptic in order to prevent the introduction of germs. Even a soft-rubber catheter must be introduced very gently, because the mucous membrane of the bladder is very apt to be congested, and bleeds readily under such conditions.

Counter-irritation is useful in very many cases. During the first stages of an acute myelitis the application of dry cups along the spinal column may be attended with some benefit. Vigorous counter-irritation with fly blisters is indicated at a later period, but these do not promise much improvement after the disease has become stationary. In this connection I may mention that in a case of chronic myelitis in which all hope of recovery had long been abandoned, I noticed that a remarkable degree of permanent improvement followed the development of a large carbuncle on the back.

The actual cautery is also recommended. I have never seen any benefit from its use, except in rare cases of compression-myelitis. In such cases, however, it sometimes acts with remarkable rapidity.

Among other non-medicinal agents may be mentioned baths and electricity.

As a rule, the patient cannot tolerate extremes of temperature. I usually recommend a sitz bath at a temperature of 100° to 110° F., in which the patient remains for from fifteen minutes to half an hour. If spastic phenomena are well marked, the bath may be as hot as can be borne by the patient. When the spastic phenomena are not prominent, the patient may receive a full bath at a somewhat lower temperature. It is well in such cases to follow the bath with rubbing and massage.

Electricity, when faithfully and persistently applied, is often productive of excellent results. It is employed either as a spinal current or directly to the paralyzed or contractured parts. When applied to the spine one large electrode should be placed over the site of disease, the other on some indifferent part of the body or spine, and they should be held constantly in position for from three to five minutes. The direction of the current seems to be immaterial. Much better results are obtained from applying the current directly to the paralyzed parts. In the majority of cases the galvanic current is preferable, but the faradic current may be used when the muscular contractility remains normal. The current should be merely strong enough to produce visible contraction of the paralyzed parts. The constant stabile galvanic current is used in the treatment of contractures, the electrodes being applied directly over the nerves supplying the contracted muscles. At the same time the interrupted galvanic or faradic current may be applied to the antagonists. In my own experience very little, if any, benefit has been derived from spinal galvanization; but, on the other hand, I have obtained most excellent results from the patient, persistent use of local electrization.

This even holds true of cases of marked contractures of the lower limbs, but a good deal will then be gained by the electrical treatment combined with tenotomy of the contractured parts.

Medicinal treatment does not play a great part in the management of this disease. Ergot has been highly recommended in the acute stages, and hypodermic injections of ergotine have been employed at the onset of hemorrhagic myelitis. I have never seen the slightest advantage from its use, and have abandoned it altogether. Iodide of potassium has also been recommended very highly, and Dr. Gibney speaks in the most favorable terms of its administration in large doses (even ʒ i–ij, t.i.d., in children), in the compression myelitis of Pott's disease. It is very difficult to form an opinion upon the value of this agent in myelitis, though it has seemed to me to exercise a certain amount of beneficial effect. But I have employed it so faithfully, and with such little effect, in Pott's paraplegia, that I am compelled to deny any special influence in this form of the disease. Weir Mitchell has recommended suspension in this disease, but further experience has not shown that this measure possesses much value.

Strychnine is the only medicinal agent which has seemed in my hands to have a decided influence on the course of the disease. This drug may be administered as soon as the acute symptoms have ceased to advance, and it is by no means contraindicated by the occurrence of spastic symptoms. The dose may be raised gradually from gr. $\frac{1}{48}$ to gr. $\frac{1}{12}$, t.i.d., and may be given continuously for months.

So long as any improvement is observed, the patient should be kept as quiet as possible. Later, gentle exercise may be allowed, but the patient must not be permitted to tire himself. Sexual intercourse is particularly to be avoided. Even after the condition of the patient has been stationary for a long time, benefit is sometimes derived from another course of treatment with electricity, counter-irritation, and strychnine.

Leopold Putzel.

SPINAL-CORD DISEASES: POLIOMYELITIS ANTERIOR, ACUTE AND SUBACUTE.—Under this name we recognize a form of paralysis which occurs, as the name implies, most frequently in young children, especially during the period of first dentition. It is by far the most common form of paralysis to which children are subject and presents a well-marked clinical picture. A healthy child is suddenly found to have lost the use of one or more extremities, or of some individual muscle of an extremity. This loss of power may or may not have been preceded or accompanied by febrile disturbance; occasionally convulsions have ushered in the paralysis, but never is the latter accompanied by loss of sensibility. Any of the voluntary muscles of the limbs or trunk may be affected, but the functions of the bladder and rectum are left undisturbed. Such is a general description of the onset of the disease. Soon, however, many of the affected muscles begin to recover their power; this recovery may be almost complete, the paralysis being finally limited to a few individual muscles; or, on the other hand, the greater part of the muscles originally affected may remain paralyzed, and later on undergo atrophy and degeneration. In this atrophy and retardation of growth the bones take part, giving rise to shortening of the affected extremity, while other deformities occur as a result of the unopposed action of the healthy antagonists of the disabled muscles.

Synonyms are numerous, and owe their variety to the views held by different observers as to the nature of the disease, before its pathology had been established. They are: Infantile spinal paralysis; Spinale Kinderlähmung (Jacob von Heine); Paralysie spinale; Paralysis infantilis spinalis; Infantile paralysis; Kinderlähmung; Paralysie infantile; Paralysie des petits enfants; Essential idiopathic or functional paralysis of children; Paralysie essentielle de l'enfance (Rilliet and Barthez); Essentielle Kinderlähmung; Dental paralysis (Underwood, 1784); Poliomyelitis anterior acuta; Acute inflammation of the anterior gray horns of the spinal cord (Kussmaul); Téphromyélite antérieure aiguë (Charcot); Acute atrophic spinal paralysis; Paralysie atrophique graisseuse de l'enfance (Duchenne); Regressive paralysis (Barlow); Myelitis of the anterior horns (E. C. Seguin). These various terms were intended by their originators to indicate what appeared to be prominent clinical or pathological characteristics of the disease. Without entering upon the question as to the relative value of a clinical, as compared with a pathological, designation of diseases, there is no doubt that, of all the terms applied to the affection, the best of the first class is that adopted by Heine (Spinale Kinderlähmung, or infantile spinal paralysis). It is true that here even the word spinal would indicate, in a general way, the anatomical location of the lesion which is the cause of the clinical manifestations; but, inasmuch as it serves to distinguish this form of paralysis from other paralyses of cerebral origin, we can pardon this slight offence against unity in terminology in consideration of the completeness with which it serves to distinguish the disease. Of the purely pathological terms we should prefer poliomyelitis anterior acuta, as indicating the seat of the lesion, the term acute being especially applicable to the disease as it occurs in children. Seguin's myelitis of the anterior horns purposely omits the term "acute," in order to include the subacute and chronic cases of the disease which sometimes occur in adults. The designation essential or idiopathic paralysis can certainly no longer be applied to a condition which has so well defined a pathology as poliomyelitis anterior; and it seems inexcusable that so excellent a pathologist as Niemeyer should have retained this inaccurate term in the seventh edition of his work, published in 1867, at a time when the gross lesion had already been demonstrated.

Historical Account.—This disease has in all probability affected children for hundreds of years, without being differentiated by medical writers from other forms of paralysis. As early as 1784, however, Michael Underwood[1] described a form of paraplegia which occurred in teething children, and especially in those suffering from bowel troubles, which in its clinical history resembles the disease now known as infantile spinal paralysis. In 1836 John Badham,[2] of London, described a similar affection occurring in children, which he considered cerebral in origin. Notwithstanding these publications, the condition did not receive general clinical recognition until, in the publication of J. von Heine's[3] great monograph, entitled "Beobachtungen über Lähmungszustände der unteren Extremitäten und deren Behandlung," 1840, the symptom group of the affection was clearly defined and this form of paralysis distinguished from other forms of paralysis occurring in children. The picture of the affection in question, which Heine gives us in the very first edition of his work, is so accurate in detail that later clinicians had but little to add to the symptomatology of the disease. But, although no objective or subjective manifestation of the disease escaped the notice of this accurate observer, yet he remained ignorant as to the true pathogenesis of the affection. So logical a mind, however, could not but suspect that the disease was the result of an actual lesion of the nervous system, and accordingly we find him indicating the spinal cord as the most probable seat of the lesion. In the second revised edition of his work[4] he terms the disease Spinale Kinderlähmung, or infantile spinal paralysis. Duchenne, de Boulogne,[5] in 1855, besides accurately describing the affection, took a great stride in the direction of precision in diagnosis as to the character and extent of the paralysis, by discovering the relation which the faradic current bears to muscles which are the seat of this paralysis. Here, then, the first stage in the history of the disease may be said to have been completed. But, although clinically the affection was established upon a firm basis, its pathology was yet unknown. Rilliet[6] and Barthez,[7] basing their statement upon negative findings in cases of this disease upon the autopsy table, considered the affection primarily a muscular one, and hence termed it essential paralysis of children, the term essential referring to the idiopathic or non-organic nature of the paralysis. Although this view gained many followers, and some of eminence, yet it was not long before positive findings upon the autopsy table exploded this theory as to the pathogenesis of the disease. In 1863 von Reinecker and von Recklinghausen[8] published the autopsy of a case in which both lower extremities had been the seat of infantile spinal paralysis. Upon a macroscopic and minute examination of the cord it was found that the ganglion cells of the anterior gray horns and the nerve fibres of the antero-lateral columns of that portion of the cord which gave origin to the nerve fibres supplying the paralyzed extremities had undergone atrophy and degeneration (*Deutsche Klinik*, January 31st, 1863). The accuracy of these pathological data was confirmed by similar findings by Cornil,[9] Bouvier and Laborde,[10] Prevost,[11] Lockhart Clarke,[12] and later on by Charcot[13] and Joffroy,[14] Vulpian,[15] Roger and Damaschino,[16] and others.

We cannot close this brief historical account of the affection without reference to the studies of Erb,[17] as to the reactions produced by the galvanic current upon the muscles which are the seat of this spinal paralysis. Finally, we should refer to the identity of this affection, as far as the pathology is concerned, to a similar but more chronic affection, occurring in adults, which was first mentioned by Duchenne fils[5] in 1872, but not thoroughly studied until E. C. Seguin,[18] in 1877, devoted an admirable monograph to the subject. In the last few years many writers have sought to ascribe an infectious character to this disease. This has been based not so much upon bacteriological or pathological findings, but upon the fact that the disease has been found to occur in occasional epidemics, one specially reported by Medin.

Other observers, like Marie, Strümpell, Seligmüller, have reported smaller epidemics. Some have reported the occurrence of the disease in several members of the same family.

PATHOLOGY.—The anatomical seat of the primary lesion of this form of paralysis is the spinal cord. This has been positively determined by numerous autopsies. It consists of an inflammatory process, acute in character, affecting in the first instance the anterior horns of gray matter. The lesion is at first diffuse, but as soon as the acuteness of the inflammatory process subsides it becomes limited in its longitudinal extent to circumscribed portions of the cord, in which even at the outset the inflammation had been most intense; this is most apt to be about the cervical and lumbar enlargements. At these points further changes soon occur, the most important of which are destruction and atrophy of the large multipolar ganglion cells situated in the anterior cornua.

This destruction and atrophy are not limited to the cells, but involve the nerve fibres in this region, and even the cells and nerve fibres of the posterior horns may become involved; sometimes the lesion extends into the white substance of the antero-lateral columns. As a result of the primary lesion in the ganglionic cells of the anterior gray cornua, we have secondary changes taking place in the nerves which take their origin from the affected portion of the cord, and in the muscles to which these nerves are distributed. These changes are atrophic and degenerative in character.

Spinal Cord. I know of no autopsies showing the condition of the spinal cord during the acute stage of infantile paralysis, inasmuch as the disease of itself is rarely, if ever, fatal. We can therefore make no positive statement as to the condition of the nerve centres during this acute stage; we can conclude, however, from our findings later on, that the disease is, in the first instance, an acute parenchymatous inflammation affecting chiefly the ganglion cells of the anterior horns of gray matter in the cord (Charcot).[19] When the autopsy has been made within two years after the onset of the disease, but slight changes can be observed in the cord by the naked eye, although the microscope reveals decided and constant alterations. These changes are typically shown in a case examined by Dr. Fred. Taylor, the particulars of which were presented to the London Pathological Society. It was that of a girl, three years of age, who suddenly became paralyzed, at the age of fifteen months, in the left leg. The paralysis was supposed by the friends to be the result of a blow; the principal symptoms observed at the time of the onset were fever and pain in the left lower extremity, followed by paralysis, and, later on, the development in the paralyzed member of the ordinary clinical phenomena of infantile spinal paralysis. The child was treated by galvanism for five or six months, and the paralysis somewhat improved; but at the age of three years death resulted from bronchopneumonia. Post-mortem examination of the spinal cord showed a diminution in the size of the transverse section of the left half of the lumbar region of the cord. This diminution was most marked anteriorly, although also observable in the left posteror horn of gray matter. The anterior roots of the spinal nerves at this level were smaller than the corresponding roots on the right side. The posterior nerve roots were unaffected. On microscopical examination of a section taken from this portion of the cord it was found that there were but few ganglion cells in the left anterior cornu, and even those remaining were ill-defined and smaller in size, paler in color, and possessing fewer and shorter processes than those of the right side. The absence of these cells was most marked in the external and median groups of ganglion cells.

The nerve fibres passing from the anterior root to the cornu of the affected side were diminished in number and size. The main substance of the anterior horn consisted of a very dense and felt-like tissue, made up of matted fibres, "an increase and condensation of the normally open and spongy basis-structure of the part." In this felt-like structure the remaining nerve cells were embedded; no granular corpuscles were visible. The white matter of the left antero-lateral column was found denser, the connective tissue being increased; while the nerve tubules were smaller than usual and deficient in axis cylinders.

This case shows the most prominent changes found in the cord in cases in which the autopsy has been made comparatively early. Occasionally areas of softening are found, more or less well defined, in different portions of the anterior horns, and at such places there is generally a total absence of proper nerve tissue, ganglion cells, and nerve fibres; but instead there is a low form of connective tissue, filled with large numbers of leucocytes and simple nuclei. In these recent cases the blood-vessels are found dilated. The cord may be affected at any level, although the cervical and lumbar regions are most frequently the seat of permanent lesion. The severity of the inflammatory process varies greatly, so that in some situations there is almost complete recovery, while in other places there is utter destruction, degeneration, and atrophy of nerve cells and fibres. The ganglion cells have been found in all stages of various forms of degeneration; many of them are entirely destroyed, and those that remain are found in a condition of extreme atrophy, having suffered great contraction and diminution in size, the cell processes, and frequently their nuclei, being destroyed. Sometimes the atrophy is of the pigmentary variety. In a case reported by Dr. Humphreys,[20] of Manchester, the number of the polar cells remaining in the affected portion of the anterior horns was compared with the number in the corresponding healthy portion of the cord, and it was found that while on the healthy side there were fifty-two ganglion cells, on the diseased side there were but thirteen.

Should the autopsy be made, as more frequently happens, many years after the original lesion has taken place, we would find changes similar in character to those described, but further advanced in a retrograde direction. The changes can be admirably studied in a collection of autopsies reported by Seguin in his work, and quoted and amplified by Seligmüller in his article on this subject in Gerhard's large work on "Diseases of Children." These changes are now readily appreciated by the unaided eye. The affected portion of the gray anterior horn is apt to be markedly shrunken and atrophied; sometimes even the posterior gray horns will be found slightly smaller than on the opposite side. The white columns, and especially the antero-lateral columns, are found atrophied and sclerosed, sometimes to a limited extent on a level with the lesion, at other times to some distance above and below the lesion; indeed, the transverse section of the cord on the affected side will show a general diminution in size as compared with that of the healthy side. The anterior nerve roots at the level of the lesion are apt to present a grayish, translucent appearance and a diminution in size.

The microscope also shows the more complete atrophic changes which the nerve tissue has undergone; the diseased portion of the atrophied anterior horn is found to contain but few or no multipolar ganglion cells, and even those remaining are shrunken, with their processes atrophied, and found to have undergone various stages of granular and pigmentary degeneration. These cells have been replaced by connective tissue which has become contracted and hardened.

The changes in the white columns are apt to be less marked, although, as already stated, there is some diminution in the size of the antero-lateral column, to a greater or less extent, above and below the lesion. These changes can scarcely be termed sclerosis. They consist of a certain degree of hyperplasia and contraction of the connective tissue, and an increase of the nuclei of the neuroglia. Amyloid corpuscles are also found. The anterior nerve roots undergo a more decided atrophy than the antero-lateral columns; the number of their medullated nerve fibres is decidedly diminished. Many of them have lost their myelin, leaving only the axis cylinders, and, as a whole, the nerve root has become thinner and of a grayish and translucent appearance. The diseased foci in the gray matter are apt to be quite sharply defined, although at the onset of the disease large portions of the cord, above and below the areas of softening, are found congested; these portions, however, are not the seat of destructive changes, and they recover as soon as the inflammatory process subsides. This probably corresponds to the regression which occurs in the symptoms, thus leaving only those muscles paralyzed which derive their nerve supply from the softened areas.

All of these degenerative changes in the cord which I have described as characteristic of poliomyelitis anterior acuta take their origin in an inflammatory process in the vascular (arterial) system of the spinal cord. Such inflammatory changes are found even in the large blood-vessels of the cord, even in the walls of the arteria spinalis anterior and its branches (Socki). Manfredi, Widal and Besançon, and others have produced degenerative changes in the anterior horns of the spinal cord of animals by injections of pure cultures of various microbes. Widal was successful in producing the lesion in seven out of one hundred and seventeen rabbits which he had inoculated with streptococci. Thonot and Masselin believe that the coli bacilli can produce the lesion.

Schultz (1901), in a recent case of this disease in which the onset resembled meningitis, but the subsequent history and, months later, autopsy showed it to be a case of poliomyelitis anterior acuta, obtained by lumbar puncture the spinal fluid and isolated therefrom the meningococcus of Weichselbaum-Jaeger. The occurrence of this disease as a complication or sequel of the acute infectious diseases, such as measles and scarlet fever, would lead one to suspect that this form of inflammation of the cord, like the types of cerebro-spinal meningitis, may be the result of a mixed infection of the primary disease infection and the various pus organisms. Some observers have been led to believe that the toxins of various infections in distant parts of the body may be carried to the cord, and set in motion the inflammatory changes in the blood-vessels which result in the degenerative changes in the anterior horns of the cord.

Changes in the Paralyzed Muscles.—Within a few weeks after the paralysis has taken place the paralyzed muscles become the seat of characteristic pathological alterations; not only do they become atrophied and smaller in size, owing to disuse, but they undergo active degeneration. Portions of such muscles can be obtained for examination by means of an apparatus like Duchenne's trocar, so that the various stages of degeneration can be studied. The first stage in the degeneration is, undoubtedly, ordinary atrophy of the muscle fibres. The fibres are narrower and diminished in diameter, the transverse as well as the longitudinal striations are finer and apparently more numerous. This apparent increase in the number of the transverse striations is due to the diminished thickness of the contractile discs. These phenomena are seen in muscles that have become atrophied from disuse, and are not distinctive of atrophy due to spinal-cord lesions.

In infantile spinal paralysis, however, the muscles soon begin to show further changes. Certain portions of the degenerating muscles begin to lose their striations entirely; here and there we find contractile discs replaced by granular matter, until the whole fibre has become to a great extent granular. This granular matter is probably protein in character, being at first soluble in acetic acid and insoluble in ether; later on, however, the granules are found to be insoluble in acetic acid and soluble in ether, which shows that the protein granules have been replaced by fatty matter. Here and there will be found pigment granules. The muscle corpuscles are found to have increased in number, and in fibres which have undergone a complete granular fatty degeneration we shall find no trace of proper muscular tissue, the fibres being replaced by these muscle corpuscles embedded in a mass of fat granules surrounded by the sarcolemma. This may be termed complete muscular degeneration, and is the inevitable fate of muscles which have not recovered in the earlier stages of ordinary atrophy. Some of the muscles thus degenerated become the seat of further changes. The connective-tissue corpuscles found in the endomysium and perimysium increase largely in number, and form themselves into fibrous connective-tissue bands, which compress the degenerated muscular fibres; gradually the fat is absorbed, and what was formerly muscular tissue has become a firm fibrous cord. This change is known as cirrhosis of the muscles, and does not occur until long after the muscles have undergone hopeless degeneration. These fibrous bands are apt to undergo contracture, which results in structural shortening and deformity. Rarely the connective-tissue corpuscles, contained in the fibrous bands, in their turn become distended with fat, thus giving rise to a deceptive fulness instead of the previous atrophy. This second fatty deposit may be so great as to lead to a diagnosis of pseudohypertrophic paralysis. When such a deposit of fat does occur it is in infantile paralysis of long standing. The ligaments and bony structures also take part in the general lowering of vitality which characterizes the paralyzed limb. The bones do not grow with anything like the vigor of the corresponding bones on the healthy side. This retarded growth results in diminution in the length as well as in the thickness of the bone; the prominences, ridges, etc., are less marked; the bone is more readily bent; closer examination shows that the compact tissue is relatively diminished, while the cancellous tissue is coarser and has scattered through it a larger number of fat cells. The bones are thus softer, but microscopically no changes in the structure of the bone tissue are found. All this results in a weakening as well as a shortening of the bone, and, necessarily, of the limb. Seeligmüller considers this bony change mostly the result of the disuse which is necessarily connected with the paralyzed member; the fact, however, that these atrophic bone changes are noticed in limbs in which the paralysis is insufficient to interfere with the adequate use of the member, would militate against this view, apart from the fact that the changes indicated seem to be far more radical than would be accounted for by ordinary functional atrophy due to disuse.

Partly in consequence of this bone atrophy, and partly as a result of the relaxation of the ligaments and muscles, the joints are apt to become altered. In extreme cases the ends of the bones which form the joint are not in contact, but hang apart from each other, so that the finger can almost invaginate the skin and ligaments between the joint surfaces. As a result, the articulation admits of abnormal mobility—motion resulting in subluxation of one joint surface upon the other. These changes are most readily observed where a muscle which passes over a joint is more or less completely paralyzed; thus, when the deltoid is paralyzed in the arm, the shoulder-joint is apt to show the above-mentioned changes very markedly. No pathological changes have been observed in any other organs of the body.

ETIOLOGY.—From modern investigations we are led to believe that poliomyelitis anterior is an infectious disease occurring sporadically, although rarely also in epidemics. Whether the disease has for its causative pathological agent a specific germ or its toxin, or whether it can be produced as a result of the activity of various germs, such as the pus organisms, etc., is not yet determined. That the disease is an infection is most probable, and from this starting-point all other factors in etiology are to be viewed as subordinate. Poliomyelitis anterior acuta is no exception to the rule in the obscurity of its etiological chapter. We know little or nothing as to the causes which produce the disease. We must, therefore, satisfy ourselves with an inquiry as to the causal relation borne by certain conditions, which precede the appearance of the paralysis, to the more or less acute inflammatory process in the anterior horns of the spinal cord. Before proceeding to this study there are certain factors which can be eliminated, and thus limit the field of inquiry.

Infantile spinal paralysis is by far the most frequent form of paralysis to which children are subject. Jacob von Heine found, among 192 paralyzed children, 158 suffering from this disease.

The disease in its acute form is peculiar to childhood, and is most frequent in the first, second, and third years of infant life. Duchenne the younger has noted one case occurring at the early age of twelve days. Seeligmüller has noted the oldest of his seventy-one cases as six years, but almost ninety per cent. of all cases reported were under three years of age. Sex is not a predisposing cause, the sexes being affected with about equal frequency.

The disease is found all over the civilized world, so that climate can scarcely be considered as exerting a predisposing influence, nor does the season of the year make any difference, cases occurring indiscriminately at all seasons. Wharton Sinkler (*Amer. Journal of Med. Sciences*, April, 1878) states, however, that forty-seven out of fifty-seven cases occurred in the warm months of the year.

Heine has stated that the disease most frequently affects strong, healthy children; and, indeed, one who sees many of these cases cannot fail to have observed many large, robust little patients whose otherwise handsome physique has been deformed by an attack of poliomyelitis anterior. But, on the other hand, most observers find that the majority of cases occur in children who are weak and delicate, even if a strumous constitution cannot generally be affirmed of them.

One of the most frequent causes assigned by mothers for this disease is "catching cold," particularly exposure to the direct action of a "draught." Or another very common cause, as stated by the parents, is a fall from the arms of the nurse or from a chair. Whether a traumatism of this kind can give rise to infantile spinal paralysis proper is questionable. It is conceivable that spinal paralysis, resulting from hemorrhage into the gray matter of the cord, may follow a traumatism; but this is not poliomyelitis anterior, although the clinical symptoms may be those of the latter disease, and it may be impossible to differentiate these cases from those of inflammatory origin.[20]

The disease being one of the first dentition period, it is natural to look to conditions connected with this process for etiological factors in its production.

There is no question that the process of dentition throws the nervous system of the child into a state of exalted irritability, during which eclampsia, tetany, and other neuroses are commonly observed. These nervous phenomena are chiefly conditions of exalted nervous irritability, in which it is conceivable that the gray ganglion cells of the cord take part. From this irritated condition it is only a step to inflammation. Henry Kennedy has called this disease dental paralysis (*Dublin Quarterly Journal*, vol. ix., February and May, and vol. xxii., August and November). The restlessness of children while teething, the disturbed nutrition, want of sleep, and febrile disturbances common to this period of life, all are sufficient to render the spinal cord more sensitive to slight active causes, such as refrigeration, etc.

It may be objected, however, that all of these influences would affect the spinal cord as a whole, while in this disease only the anterior gray columns of the spinal cord are primarily affected. This might be explained by reference to the fact that motor areas of the cord in infants are much more in demand and further developed than the sensory tract. Infants are in constant motion, the extremities are thrown about whether in health or disease; during the waking hours infants constantly move and throw about the limbs and body; as a result the centres for these movements are supplied with an excess of blood, and hence are more prone to take on inflammatory processes.

Acute febrile conditions are commonly assigned as causes for this disease. It must not be forgotten, however, that the disease is in very many cases ushered in by fever, which is a symptom of the inflammation, and cannot be considered an etiological factor. But there are many cases which occur during the course of, or follow upon, the acute exanthemata—scarlet fever, measles, and typhoid fever. Such cases must be carefully distinguished from postdiphtheritic paralysis, the more so since diphtheria often complicates scarlet fever, measles, etc. Duchenne and Seeligmüller report two cases following upon vaccination.

In many of the cases careful inquiry into the family history of the patient will reveal the existence of nervous affections in other members of the same family—either paralysis, convulsions, or insanity. Thus I have seen infantile spinal paralysis of the leg in a little girl, and paralysis of the upper arm in a younger brother of the first patient.

SYMPTOMATOLOGY.—In discussing the symptoms of this disease it is perhaps wise to take up in order the characteristics of the invasion, the appearance of the paralysis, and lastly, the deformities and contractures resulting from the paralysis.

First, the Stage of Invasion.—Although various prodromal symptoms have been laid down in the text-books as preceding the onset of the disease, yet none of these appears to me to be peculiar to this affection, even in slight degree. The children are irritable, slightly feverish, and suffer from loss of appetite; the bowels are constipated or relaxed; some of the little patients complain of pains in the back and limbs. One observer[21] has noted that these patients refuse to walk, or, if they walk, are easily made tired and wish to be carried. I myself have not noticed the latter symptom as part of the history of my cases, and have found very many cases—indeed, the large majority of my cases—in which no prodromal symptoms at all occurred. Cases may be divided, as regards the character of the invasion, into two classes: First, those in which the onset is shown by high fever, with or without convulsions; second, those in which the stage of invasion is entirely absent, the patient becoming suddenly paralyzed.

Cases belonging to the first class will be found to have either the febrile disturbance or the nervous symptoms most prominent. The patient is suddenly attacked by high fever, 100° to 102° or 103° F., rarely above; there are great thirst and restlessness. At the beginning of this fever there may occur a convulsion lasting a short time, and often followed by others, or the fever may be slight; but the child lies in a state of semi-coma for a few days, from which it gradually rallies, when the friends find one or more groups of muscles, or one or more limbs, paralyzed. The fever may last from a few hours to two or three, or even more, days; but, as a rule, it continues only a few days, after which it subsides, and the parents believe the child to be on the road to recovery. Then suddenly paralysis is discovered to have taken place. If the paralysis is slight, it may not be noticed until the initial fever has long passed, so that the parents will assure the physician that there was no fever before the onset of the paralysis.

In cases occurring during the course of convalescence from measles or some other acute febrile affection, the paralysis is supposed by the friends to be due to the general disease.

In many of the cases, in addition to the fever, with or without convulsions or semi-coma, the patients suffer from diarrhœa and often from vomiting. Hyperæsthesia of the limbs and other portions of the body may also occur. There may be frequent micturition, but there is never paralysis of the bladder or loss of sensation.

The cause of the initial fever would appear to be the acuteness of the inflammatory process in the cord. W. Vogt,[22] however, considers the lesion in the cord a result, rather than a cause, of the fever. The fever is not a constant accompaniment of this disease; it was present in about one-half of my cases. Frequently parents do not notice the fever, which may occur at night, when the child is asleep. When the little one awakes in the morning the paralysis is observed, although the fever, if only of a few hours' duration, may have been overlooked. The antecedent fever is noted, however, in the cases in which it is of longer duration. It has been known to last for twelve days; but in most cases it is of less than two days' duration, and commonly lasts only twenty-four hours. The temperature rarely rises above 103°, or, at most, 104°, and even these figures are exceptionally high. We have no good thermometric records; the diagnosis being never possible before paralysis has set in, and the fever has, as a rule, come to an end, although cases have been reported in which the fever lasted after the paralysis was complete.

Convulsions occur, in the opening stage of this disease, in many cases in which fever is present, and also in some in which there is no rise of temperature. This would seem to prove that the convulsions are not dependent upon the cerebral hyperæmia produced by the fever. It is, furthermore, not probable that these attacks, which are epileptiform in character, are due to lesions in the spinal cord, for the muscles which become convulsed are not only those that are afterward found to be paralyzed, but impartially those of the whole body. Some writers, however, state that the convulsive movements are more violent in those muscles which afterward become paralyzed. The attacks vary in duration, number, and frequency. Frequently only a single convulsion ushers in the disease; at other times the patient is thrown into a status epilepticus lasting some hours, and it is conceivable that in this condition the patient may die, the diagnosis of poliomyelitis not having been made. On the other hand, the convulsion may be so slight as to be entirely overlooked, and, if it take place during the night, the fever as well as the convulsion may be entirely overlooked. The recovery from the convulsion may be complete, or the child may fall into a stupor, and even coma, from which it only emerges when all acute symptoms have disappeared. Frequently the little patient has no convulsions, but still is restless and trembling, or apathetic and drowsy. Either of these conditions may be present in the opening stage of the disease, with or without the fever.

Another symptom, to which we must call attention, is one which accompanies all febrile conditions, but is here particularly prominent, namely, hypersensibility—the patient cannot be touched without feeling pain—he cannot be moved without crying out. Some writers have stated that this exalted sensibility is most marked in the spinal column. My own experience does not show that the little patients ever complain of a sensitive spine. On the contrary, I have found these children very easily handled, and the spine very flexible, this fact forming one of the data for the differential diagnosis between this disease and Pott's paraplegia, although patients may have passed through the initial stage of the malady with more or less of the above symptoms, or so little of them as to escape the observation of the friends; yet the

Second, or paralytic stage, is never omitted, and is, in fact, "the disease" (Rilliet and Barthez). The paralysis may develop very suddenly, the child being paralyzed almost as rapidly as though from apoplexy, or it may develop more slowly, the paralysis gradually extending in the course of one, two, or three days. In the first class of cases a large number of the voluntary muscles of one or more limbs become paralyzed simultaneously; in the second class of cases the paralysis extends from one group to another until the maximum paralysis has been attained. Sometimes the paralysis is so complete that the patient lies without being able to move a muscle. At other times the paralysis is so slight that it is unnoticed until the function of the paralyzed member is interfered with.

However complete the paralysis at first may be, yet it is characteristic of this disease that after a short time (one or more days) many of the paralyzed muscles begin spontaneously to recover their power; this is known as the regression of the paralysis. Spontaneous recovery from the original paralysis may be complete in certain individual muscles, although entire recovery for all the muscles never occurs. Many writers state that in most cases the height of the paralysis is attained at the end of twenty-four hours. My experience leads me to give a longer period for the development of the palsy, certainly not longer than a few days, when the paralysis will cease to extend. Regression, however, begins in many cases as early as the second day, continues rapidly for the first few weeks, then much more slowly, although even up to four or five months the muscles may still undergo spontaneous recovery of power. Any power restored after that is due either to the good effects of treatment or to the use of the limb. However complete the restoration of some of the paralyzed muscles may be, it may be positively affirmed that complete recovery in all the muscles affected by infantile paralysis is impossible.

Muscles affected: All the voluntary muscles of the body may be the seat of this paralysis, except those of the head (Seeligmüller reports one case in which the muscles supplied by the facial were affected), eyes, ears, mouth, pharynx, and larynx. On the other hand, the sterno-cleido-mastoid has been found affected, the muscles of the trunk, including those of the back and abdomen, and, above all, the muscles of the extremities.

The paralysis may affect the back, so that the patient cannot sit or stand; the neck, so that the head falls forward or to the side, and it may affect one or more extremities, giving rise either to crossed paralysis (one arm and the opposite leg), or paraplegia (all four extremities or the two lower extremities), both upper extremities, or the arm and leg of the same side (hemiplegia).

Most frequently only one extremity is affected. Next in order of frequency comes paralysis of both lower extremities, while crossed paralysis and hemiplegia are much rarer. The upper extremity is less frequently affected than the lower, while paralysis of all four extremities is extremely rare, but three cases having been reported in the literature (see Seeligmüller).

It is extremely rare for a limb to remain totally paralyzed, nor do we find in any two cases an exactly similar distribution of the paralysis.

Certain groups of muscles will be found to have escaped the paralysis, and sometimes even portions of the same muscle will retain power, while the rest of the muscle is paralyzed.

The anterior tibial group of the leg and the extensors of the thigh are most frequently affected. The psoas, on the other hand, is rarely affected, even in the most extensive paralysis.

In the upper extremity the deltoid is most frequently paralyzed.

The sphincters of the bladder and rectum are never affected. In this respect we have an important difference between this form of paralysis and that following transverse myelitis. It is true that in some very young children the general disturbance with which the disease is ushered in may give rise to a few involuntary passages, but this is only temporary, and will not be present when the paralytic stage has set in. After the sixth to the ninth month has passed, we can no longer look forward to spontaneous recovery in the paralyzed muscles. Muscles which have not improved until then are apt to remain paralyzed, and go on to the third stage of the disease, the atrophic stage, in which extreme atrophy of the paralyzed muscles is the most prominent symptom. It must not be supposed, however, that the paralyzed muscles do not atrophy until six or more months after they have become the seat of the paralysis. On the contrary, atrophy of the fibres of the paralyzed muscles can be found with the microscope very soon (two or three weeks) after the paralysis has set in, and several authorities claim to have observed atrophy, evident to the naked eye, as early as the third week after the paralysis. In my own cases I do not remember to have observed any evident atrophy earlier than three months after the first occurrence of the paralysis. The cause of this atrophy is, as we have already seen under the head of pathology, not simple disuse of the paralyzed limb, but a cutting off of the trophic influence of the nerve cells of the anterior gray horns of the spinal cord; this results in a disturbance of the nutrition of the muscle tissue as well as organic degeneration of the nerve fibres. Disuse of the paralyzed limb undoubtedly aids in producing a diminution in the size of the paralyzed member. As a result of these causes we have a very extensive atrophy of the paralyzed muscles—so complete that frequently the configuration of the bones, with their anatomical points, can be felt or even seen with startling distinctness. Often all muscular tissue seems to have disappeared, leaving only the bones, connective-tissue bands, and skin. As already explained, however, these atrophic members in the last stages of atrophy may undergo a pseudohypertrophy, owing to the deposit of fat in place of the atrophied muscle fibres. In those muscles which undergo recovery after a certain amount of atrophy has taken place, the restoration of volume in the recovered muscle does not directly follow upon restoration to power. The muscle is only gradually restored to its former size some time after power has returned.

Atrophy is not limited to the paralyzed muscles, but affects the bones and ligaments, and even the blood-vessels; the extent and character of the atrophic changes have already been discussed. There is also atrophy of the skin; it is apt to be more delicate and thinner; it is of finer texture, and paler in color at first, although later on it becomes cyanotic in color, owing to the diminished blood supply in the paralyzed limb. This diminished blood supply is due to atrophy of the blood-vessels and the disappearance of the finer capillaries. The muscular coat of the arteries is atrophied, giving rise to a diminished arterial tension. In consequence of this diminished blood supply the surface temperature of the paralyzed member becomes greatly diminished. Fluctuation in temperature is very great, especially when the body has been exposed to cold. Thus the difference between the healthy and paralyzed limbs may be 20°, 30°, or even 40° F. It is almost impossible to keep the paralyzed limbs warm; friction and artificial heat serve to restore warmth for a time, but, unless frequently applied, they do very little good. As a result of the lowered temperature and slowness of circulation, the skin sometimes becomes the seat of ulcerations, which are very slow to heal, and are exceedingly painful. These ulcers affect only the scarf skin, and consist of a desquamation of the epidermis, the derma remaining unaffected. As part of the symptomatology of the paralytic and atrophic stage of the disease, we must devote some space to the discussion of the accompaniments and results of both of these conditions, namely, the deformities so characteristic of the final stages of this affection.

Third Stage.—Deformities Resulting from Infantile Spinal Paralysis.—A careful analysis of the deformities resulting from infantile paralysis will warrant their classification into two groups:

1. Deformities due to trophic changes in the limbs.
2. Deformities depending on the paralysis of muscles.

1. Deformities Due to Trophic Changes. In discussing the symptomatology of this disease, it was seen that, owing to destruction or interference with the trophic centres in the cord, all growth of the parts supplied by the nerves passing from the affected region was arrested, and the development which the affected tissues had attained before the time of seizure was diminished, the tissues retrograding and undergoing degenerative changes. The deformities of this group, then, are due, first, to cessation of growth; second, to retrograde metamorphosis. Cessation of growth is in every direction, and results in shortening and attenuation of the affected member as compared with the condition of the limb in health. Retrograde metamorphosis or atrophy will also cause deformity, either by shortening, or, more commonly, by attenuation; so that lack of growth, aided and reinforced by atrophy and degeneration, results in deformity by producing shortening or attenuation, or both together. From a consideration of the function of the upper, as compared with the lower, extremity of the body, it is evident that deformity due to shortening is of far more importance when it affects the lower extremity than when it affects the upper. Not only is it essential that the two limbs should be of equal length in order that the patient may walk and stand without deformity, but the proper performance of the functions of other parts of the body depends upon the lower extremities being of equal length. For, the trunk being supported by the two lower extremities acting as pillars, the shortening of one of these pillars as compared with the other will result in a corresponding lowering or sagging of that side of the body; the pelvis will become oblique, the normal side being on a higher plane; and were it not that conservative nature seeks to rectify the result of the disease, we should see these patients walking and standing with the body bent over to the side of the shortened leg. To maintain equilibrium the patient is compelled to throw the body to the opposite side, giving rise to a functional lateral curvature of the spine, which, in its turn, again in the effort to maintain equilibrium, is modified by a secondary curve. We have, then, as a result of the shortening of the lower extremity, deformity in walking and functional lateral curvature.

Atrophy and attenuation are of less importance here than in the upper extremity, disability rarely resulting from this cause alone; while, on the other hand, shortening is of less importance in the upper extremity than in the lower; for one arm or hand may be shorter than the opposing member, but were it not for the paralysis which accompanies the shortening, it would be of little importance. On the other hand, atrophy is of great importance in its effects upon the upper extremity. An atrophic shoulder will sag downward, producing even, in some cases, a lateral curvature high up. But, what is more common, the head of the humerus becoming atrophied, and the hand having no resistance below, as is the case with the foot, we have a resulting subluxation, which in itself would interfere with the use of the arm. In one of my cases this subluxation in every direction resulted from the slightest motion, and was an important element in the treatment of the case. Although, in the limits of this article, I consider it more profitable to indicate the *principles* which govern the production of deformities which result from infantile spinal paralysis, rather than minutely to catalogue all of these, I cannot here overlook a seemingly minor deformity which results from the muscular atrophy characteristic of this disease. I refer to the undue prominence of the articular extremities of the bones in cases in which the muscular atrophy has become extreme. This deformity is so marked in some cases as to lead the patients to believe that the joints are dislocated or are the seat of osteophytic growths. Although this undue prominence of the extremities of the bones does not interfere with locomotion, yet it is of great importance in the treatment of these cases; for a careless application of rigid orthopedic apparatus often results in the formation of callosities over these bony surfaces which are painful to the patient, and when once formed are difficult of removal.

The second group of deformities which result from this disease are by far the most important; they are the deformities depending upon the paralysis of muscles. Inasmuch as individual cases differ greatly as to the extent of the paralysis and the number of muscles involved, so also the variety of deformities resulting from infantile paralysis includes almost every form of inability and perverted motor activity. But before considering these deformities it will be proper to consider the laws upon which their production depends. This subject has been studied by Volkmann in the first of the "Klinische Vorträge." Although inability is the immediate result of paralysis, deformity is not the consequence of the paralysis itself, and does not occur until a later stage of the affection is reached, when it is found that permanent contractures have taken place, of which the paralyzed muscles are generally, but by no means exclusively, the seat. As to the cause of these contractures which so deform the already paralyzed limb, many explanations have been advanced. The oldest and most popular is that of unopposed muscular action. This explanation rests upon the theory that all muscles in their quiescent state are the seat of a reflex tonicity. That is to say, it is supposed that the higher centres of the brain and spinal cord are constantly sending out innumerable and minute impulses in response to constant and unconscious peripheral excitation. This constant state of contractility is known as the reflex tonicity of the muscles, and, being constantly present in all of the voluntary muscles, the parts moved by them are kept at rest except when the will or reflex causes throw excess of energy into any single group. The principle is similar to that by which the heavenly bodies are enabled to retain their places in the universe, although constantly acted upon by centrifugal and centripetal forces.

Reasoning from this assumption, it is supposed that as soon as any group of muscles is cut off from the motor centres in the cord, the opponents, being still the seat of the normal muscular tonus, undergo contracture because the equilibrium has been destroyed. Were such the explanation, however, we should expect immediately after the paralysis to see the remaining healthy muscles become permanently contractured. Volkmann did great service in combating this theory, although he has gone to the opposite extreme and proposed one almost equally untenable. He found that in children with infantile paralysis of all of the muscles of the lower extremity, in which the muscular groups on the anterior as well as those on the posterior portion, or calf of the leg, were paralyzed, the tendo Achillis was the seat of contracture, and the foot assumed the equinus position, just as though the anterior tibial group alone had been paralyzed and the calf muscles had remained intact. Again, in cases of talipes equinus, immediately after the performance of tenotomy of the tendo Achillis, if the child were placed in a chair with the legs pendent, the foot, instead of assuming the calcaneus position, in obedience to the unopposed action of the anterior tibial group, is found to place itself in the equinus position; this is explained by the action of the force of gravity upon the foot. On the strength of both of these observations he explains the production of the deformity in many cases by the action of the force of gravity, claiming that the position which this force compels the paralyzed limb to assume, as the patient sits or stands, will be the position in which contractures will most frequently fix the limb. But on consideration we find that, even in the extremity on which the force of gravity is most influential, namely, the foot, this theory is not substantiated; for which one of us has not seen an acquired talipes calcaneus with toes raised and heels bulbous and boring the ground? The study of a recent case of facial paralysis will help to clear up this subject.

It will be found that, after the paralysis has occurred, as soon as the patient has made the first use of the nonparalyzed side, the face is slightly drawn to the healthy side. I say slightly, not so completely as it would necessarily be if the cause of the deviation were the unopposed action of the healthy side, but just enough to make it noticeable. This deviation, I think, can be explained in the following manner: The first facial motor impulse that occurred immediately after the paralysis had taken place found only the healthy side of the face ready to act. It contracted, and as soon as the motor impulse ceased the tissues returned to their relaxed condition; this passive relaxation is almost, if not quite, sufficient to restore the tissues to the position they occupied before contraction. The residual work necessary to complete the restoration the opposing muscles do for each other, and since in our supposititious case the opponent was paralyzed, the healthy muscles had almost, but not quite, returned to their normal position. In other words, the origin and insertion of the muscles have been brought slightly nearer to each other than they should be normally in the condition of rest with increased activity. After a time the shortening will become more marked, and the muscle will assume the contractured appearance so familiar in deformities following long-standing paralysis. The paralyzed muscles, in order to adapt themselves to the contracture and shortening of the healthy muscles, become passively stretched, for it is evident that every time the activity of the healthy muscles is called into play the paralyzed opponent is stretched and becomes longer, just as the healthy muscle becomes shorter. The contracture or shortening of the healthy muscles, which is primarily the result of the use of the healthy muscles, is increased by, and at the same time the cause of, the elongation which the paralyzed muscles undergo. I conceive that the only contractures which are properly the result of the action of gravity are those in which all the muscles of the limb are paralyzed, and in these cases there is no question of the nonapplicability of the theory of muscular tonicity. There is another form of contracture of which the paralyzed muscles themselves are sometimes the seat; this is the result of the final stage of atrophy which the paralyzed muscle undergoes. Then the muscular fibres disappear, the muscles proper being replaced by connective-tissue bands; these contract, and when such contractures occur they counteract other previous contractures of the nonparalyzed muscles.

It follows, then, that paralysis of muscles causes deformity in one of two ways: first, by mere inability resulting from the paralysis; second, by the resulting contractures in the healthy or paralyzed muscles.

Deformities of the Lower Extremities.—Extensive paralysis, involving all of the muscles of the lower extremity, will produce a deformity well described as "flail-like." Here the lower extremity is so flaccid, and the patient has so little command over it, that in walking (with crutches) it swings as loosely as a flail; and yet, however complete the paralysis may be, careful examination will show here and there a muscular group of which the patient has retained the use. The psoas magnus is frequently preserved, so that the thigh can be flexed slightly, although the leg cannot be extended. Another very common deformity at the hip-joint is inability to extend the thigh because of a contractured psoas. In these cases the hip-joint cannot be extended even to a right line with the body; in cases in which the rectus femoris and tensor vaginæ femoris are preserved this deformity is increased in degree. The prominent tensor vaginæ femoris appears to be so important a factor in the production of the deformity that the effect of the contractured psoas is overlooked. Hence disappointment in the operative and mechanical treatment. When deformity occurs at the knee-joint it is generally due to contracture of the outer and inner hamstring tendons. In these cases the muscles which extend the knee are paralyzed, the ligaments of the knee-joint are weakened by disease, and hence, when the patient attempts to rest the weight of the body upon the knee-joint, it closes up like a jack-knife. When the muscles on both the extensor and flexor side of the thigh are paralyzed, it is impossible to use the knee-joint in standing or walking, and the inability is almost as great as in flail leg. The most common seat of the deformities resulting from this disease is undoubtedly the ankle and mediotarsal joints; in other words, the joints involved in the various forms of club-foot. The forms of paralytic club-foot conform more or less closely to the classical varieties. The order of their frequency is, in my experience, as follows: (1) talipes equino-varus; (2) talipes calcaneo-valgus; (3) talipes equinus; (4) talipes calcaneus.

Paralysis of both the anterior and posterior calf muscles is apt to result in the equino-varus deformity, that being the position in which the foot is for the most part held. When the anterior tibial group alone is paralyzed, the deformity is apt to be equinus or equino-varus, for reasons already stated. Paralysis of the peronei alone will result in varus. Talipes equinus and equino-varus are often accompanied by contraction of the plantar fascia. This is particularly apt to be the case if the tibialis anticus is preserved, while the rest of the anterior group is paralyzed. Occasionally one or two divisions of the extensor communis digitorum remain normal, the rest being paralzyed; the result is contracture of the preserved tendon, and hyperextension of the first phalanx of the toes supplied by these tendons. In such cases the shoe of the patient presses upon these prominent phalanges, and produces excoriations, thickening, and bunions, which can often be cured only by tenotomy. When the interossei are paralyzed we have a condition analogous to "main en griffe" of the hand, the first phalanx and all of the toes being extended and the ball of the foot prominent. Dr. N. M. Shaffer has described, under the head of "Non-deforming Club-Foot," a condition which may be characterized as an incomplete talipes equino-varus; this condition often results from infantile paralysis.

Paralysis of the posterior tibial group, including the gastrocnemius and soleus, will result in calcaneus or calcaneo-valgus, contracture taking place in the anterior group owing to the use of the healthy muscles in a limited arc. These patients walk with the toes raised and the heel on the ground; this pressure on the heel results in the formation of incurable callosities of the skin, and inflamed bursæ over the os calcis. Deformities of the upper extremities, although far less important than those of the lower extremities, are equally important when we take into consideration the disability which they cause. I have already referred to the inability caused by paralysis of the muscles about the shoulder-joint and the laxity of the ligaments in these cases. But, in addition to the disability, the pectoral muscles and latissimus dorsi become shortened, owing to paralysis of the deltoid, and the arm is held firmly adducted.

Contractures occasionally are found at the wrist and elbow joints, and their production is explicable on the principle already discussed.

In the trunk the most important deformity that can occur is lateral curvature. Not the form due to the shortening of one of the lower extremities, but a paralytic curvature—that is to say, one due to paralysis of the large or extrinsic muscles of the back, or the deep intrinsic muscles of the vertebræ. When the large muscles are paralyzed the corresponding healthy muscles of the opposite side become shorter and cause a bending of the spinal column, composed as it is of flexible segments, to the healthy side, the convexity of the curve looking toward the paralyzed side. If the curve be low down, a secondary or compensatory curve will appear high up. If the primary curve be high up, no secondary curve will be present. This is the result of the necessities of equilibrium. When the deep or intrinsic muscles of the spine are paralyzed, we have, as a result, rotatory lateral curvature, the most deforming condition the orthopedic surgeon has to deal with. The limits of this paper will not admit of the discussion of the cause of the so-called idiopathic cases of lateral curvature; but of the fact that a large number of cases of lateral curvature are the result of infantile spinal paralysis there is no doubt.

Diagnosis of Muscles Affected.—In examining a case of infantile spinal paralysis for the purpose of discovering what muscles are affected, I adopt a plan somewhat as follows: If the patient is able to walk, he should be made to do so while undressed; the movements of the various joints should then be noted and compared with those of the healthy side; any dragging, inversion, or eversion of the leg should be observed. The patient should then assume the recumbent position, and each muscle in turn must be tested as to its activity, beginning with the psoas; the leg may be raised, and the patient requested to maintain it in the raised position; or, if he is intelligent enough, the patient may be required to perform the action which will bring out the muscle under examination. In infants we are aided in this examination by a condition peculiar to them, by which the limb can be placed in any desired position, and will be retained there if the necessary muscular power is preserved, only gradually falling back to the relaxed state. This peculiarity has been compared to a similar condition present in patients under the influence of catalepsy. Finally, the patient should be examined by the most reliable and accurate test of infantile spinal paralysis, namely, the electric current. In this examination we make use of both the galvanic and faradic currents. We test the degree and kind of excitability of the nerves and muscles to both currents, and compare the result with similar tests made upon corresponding healthy muscles. In speaking of the pathology of this disease it will be remembered that the changes which the nerves and muscles undergo were thoroughly discussed. These changes were of the kind known as degenerative changes. They are not the result of all forms of paralysis, but occur only in those cases in which the lesion which is the cause of the paralysis cuts off the connection between the gray matter (anterior horns in the spinal cord, bulbar nuclei in the case of cranial nerves) and the nerves originating therefrom and the muscles supplied by them. The gray matter exerts upon the nerves and muscles what is known as a trophic influence, and it is the loss of this rather mysterious trophic influence which results in the degeneration of the nerves and muscles thus deprived. Paralysis alone does not cause degenerative atrophy, as is shown in cases of cerebral paralysis, in which the nerves and muscles, although deprived of motor power, still retain their connection with the so-called trophic centres in the gray horns of the cord.

Muscles and nerves which are the seat of degenerative atrophy give rise to peculiar electric reactions, which serve to distinguish muscles paralyzed by anterior-horn or nerve-trunk lesions. If nerves and muscles paralyzed by infantile spinal paralysis are examined five weeks or more after the paralysis has occurred, it will be found that the farado-nervous excitability is very much diminished or, later on, entirely absent. Farado-muscular excitability disappears a little later than that of the nerves. Faradic contractility of muscles is in reality the expression of the faradic contractility of the nerves which ramify throughout the muscle, so that, as soon as the faradic contractility of the nerves is lost, that of the muscles supplied by the nerves is also lost, even if the former are not yet advanced in degenerative changes.

The galvanic current yields even more striking changes. When such a current is passed through a normal nerve the muscles supplied by the nerve will contract. This contraction will be greater at the closing of the negative pole than at the *closing* of the positive pole; or, expressed in formula, this reaction will be K.C.C. > A.C.C.

The *opening* contraction will be A.O.C. > K.O.C.

In a nerve paralyzed by anterior poliomyelitis these reactions will become

K.C.C. < A.C.C., or
K.C.C. = A.C.C.

The opening contraction, if present at all, will also be reversed, A.O.C. < K.O.C.

The contraction will also be altered modally; that is to say, while the normal reaction is quick and sharp, the degenerative reaction is slow and wavering. All of these changes are known as qualitative changes; the former serial, the latter modal qualitative changes.

There is, furthermore, a quantitative change. That is to say, while a certain strength of galvanic current may be needed to produce a certain contraction in a normal muscle, a much stronger current will be needed to produce a similar reaction in the degenerated nerve or muscle. What has been said of the galvanic reaction in the nerves applies also to the muscles supplied by them.

These qualitative and quantitative galvanic changes, together with the diminution or absence of faradic contractility, make up what is known as the reaction of degeneration, and it is a most valuable diagnostic agent for the recognition of muscles affected by infantile spinal paralysis.

Differential Diagnosis.—This disease is so frequent in infancy, and has been so well studied in the past few years, that, in any given case of paralysis in children, the physician, as a rule, thinks of poliomyelitis as a possible condition. It is fortunate that we have in the symptomatology of this disease much that is positive and characteristic, so that it is possible to arrive at a positive diagnosis in almost every case.

We have to distinguish this affection in children from (1) other forms of paralysis, whether cerebral, spinal, or peripheral in their pathology; (2) paralysis following acute disease, such as diphtheria, meningitis (cerebrospinal), etc.; (3) paralysis due to toxic action of poisons, such as arsenic; (4) pseudoparalysis of rickets and marasmus; (5) deformities of congenital origin, such as club-foot and congenital dislocation of the hip; (6) atrophy and disability due to inflammatory joint disease.

Patients paralyzed from cerebral lesions present the following points of difference from those suffering from this disease: First, the history of the onset of the paralysis is different. It is that of apoplexy or of embolism occurring rapidly, accompanied by repeated convulsions, and, above all, there is the fact that the face and tongue, as well as the limbs, are affected. On examination we find a paralysis corresponding to this history; we may have (with right-sided paralysis) aphasia in older children. There is frequently loss or diminution of sensibility, the tendon reflexes are exaggerated, while in anterior myelitis these are either absent or diminished in the tendons of the paralyzed muscles, and clonus may be present. Even if the muscles of the face have recovered, these symptoms will still distinguish cerebral from spinal paralysis. Furthermore, the limbs are well nourished and not atrophied, the surface temperature is not diminished, and the contractures, if existing, are spastic in variety and present in limbs which have not lost contour through atrophy. What is most important, however, are the results obtained from an electrical examination. In these cerebral cases faradism gives good reactions in the paralyzed muscles, while galvanism gives equally good reactions, the formulas being unchanged either in quantity or in quality. On the other hand, in cases of poliomyelitis anterior we have loss of faradic contractility, while galvanism shows the reaction of degeneration in the paralyzed muscles. The electrical examination, together with the history, should certainly yield sufficient data for a positive diagnosis. It is furthermore found that children paralyzed from brain lesions are apt to show a diminution of mental power, which is never present in the patient suffering from poliomyelitis.

Diseases of the spinal cord resulting in paralysis affect directly or indirectly either the anterior gray horns, together with other portions of the cord, or do not affect these horns at all, as, for instance, in secondary sclerosis of the lateral columns. Of the first class we have transverse myelitis, compression myelitis of Pott's disease, and most probably progressive muscular atrophy, and pseudohypertrophic paralysis. Here also belong cases of hemorrhage into the spinal cord. Here electrical examination, although of some, is not of so great utility as in the differentiation from cerebral paralysis. In transverse myelitis we have a paralysis of sensation as well as of motion. There is paralysis of the sphincters, there is the appearance of bedsores, while the history shows no regression of the paralysis, and the presence of long-continued fever. In the myelitis, or rather meningitis with myelitis as a secondary affection, of Pott's disease, the anterior horns of gray matter may or may not be involved, giving rise to various forms of paralysis. When the anterior horns are involved we shall have paralysis (paraplegia) it is true, but we shall also have the symptoms of vertebral caries, reflexes not abolished, but often increased, and paralysis of the bladder. Faradic contractility is generally preserved, although when the affection of the cord is very extensive it may gradually disappear. Progressive muscular atrophy is not frequent in children, and when it does occur the gradual and progressive nature of the paralysis serves to distinguish it from poliomyelitis. There is also a peculiar "cut-out appearance" characteristic of the atrophied muscles in progressive muscular atrophy, the atrophied portions being at first isolated and sharply bounded by well-developed muscles. In pseudohypertrophy of the muscles the gradual hypertrophy which accompanies the paralysis is sufficient to distinguish this disease. In the last stages of atrophy in cases of infantile paralysis, as we have already stated, there may be a deposit of fat in the atrophied muscles, but this occurs so rarely and so long after the paralysis has set in, that the history also will be a certain guide. Hemorrhage into the anterior horns of the spinal cord, when affecting these portions of the cord alone, can with difficulty be differentiated; when it affects other portions of the cord the corresponding symptoms will be sufficient to localize the lesion.

Of diseases of the spinal cord which do not affect the anterior gray horns, the most commonly met with in children is spastic paralysis (Erb) or tetanoid pseudoparalysis (Seguin). These cases were formerly classed with those of infantile spinal paralysis, although the two diseases have scarcely a symptom in common. What has already been said of the differential diagnosis from cerebral paralysis will also apply here, the cord lesion in both cases being a sclerosis of the crossed pyramidal tracts. We have then, here, the absence of the degeneration reaction to both currents, the increased reflexes, the spastic contractures, the absence of atrophy, and sometimes diminished intelligence.

In cases of peripheral paralysis the physical symptoms, those obtained both by the electric currents and by examination, are exactly similar to those present in infantile spinal paralysis. The only important point of difference is that sensation, as well as motion, is apt to be involved in the paralysis of the affected nerve. When the patient is too young for satisfactory tests of sensation to be made, the diagnosis is extremely difficult.

In diphtheria we have the history of the disease (if the diphtheria has not escaped the attention of the patient's friends), the involvement of the muscles of the palate and throat generally, and finally the rapid recovery. We may also have ataxia and paralysis of the eye muscles. The faradic contractility is preserved.

From the paralysis of cerebro-spinal meningitis, the history and what has already been said of cerebral and spinal paralysis will serve to make the diagnosis.

Arsenic and other metallic poisons as a cause of paralysis in children must be extremely rare. I have never seen a case. E. C. Seguin has described several cases in adults in which paralysis resulted from acute arsenical poisoning, and which simulated anterior myelitis.

Cases in which rickets or marasmus have so disabled the lower extremities as to interfere with their use in locomotion are easily distinguished by the fact that there is no true paralysis; these muscles can be used, but walking is impossible, owing to tenderness and softness of the bones in the rachitic patients, and the weakness of the muscles of patients suffering from marasmus.

Congenital club-foot can be distinguished from paralytic cases by the absence of the characteristic electric reaction, and of other symptoms of infantile spinal paralysis.

The disability produced by congenital dislocation of the hips may be mistaken for paralysis, but a careful examination of the hip-joints, together with the peculiar gait and the absence of all the symptoms of this disease (infantile spinal paralysis), will serve as aids in making a diagnosis. Finally, inflammatory disease of the joints, especially of the hip, may give rise to atrophy and disability which might cause a suspicion of the presence of infantile paralysis.[23] When the history of joint disease is taken into consideration, together with the pain and swelling accompanying this condition, it will be hardly possible to be in error for any long period.

TREATMENT.—Inasmuch as there are no characteristic and pathognomonic signs by which a diagnosis can be made in the inceptive stage of the disease, before the paralysis has occurred, our treatment is necessarily one of symptoms and not rational. We treat, in other words, the fever, the convulsions, and the general conditions that may be present. But as soon as the disease itself can be diagnosticated by the presence of paralysis of motion in one or more members, the loss of reflex action, and the retention of sensibility in the paralyzed muscles, then a rational treatment can be instituted. We can attempt a derivative action to the skin by counter-irritation applied either locally to the spinal column, or to the whole of the cutaneous surface. As local counter-irritants in robust subjects, cupping and other forms of local blood-letting have been tried. Iodine may be painted along the whole length of the spinal column, or fly-blisters may be applied over the portion of the cord where the lesion is supposed to be located. General derivation to the skin may be accomplished by a strong mustard bath, repeated frequently in the course of a day. These baths, by reducing temperature, will serve to render the patient more comfortable, and will also exert a beneficial action upon the central disease. A brisk purgative may aid in reducing the congestion of the cord, and under any circumstances will benefit the general condition of the patient. Ice applications to the spine are indicated in cases in which the fever is an important factor in the treatment of the patient. The drugs which may be useful in this stage are those which antagonize the febrile movement, and those which are commonly termed antispasmodic. Of the former class are antifebrin and antipyrin, in doses sufficient to reduce temperature; among the latter are the bromides and chloral, which, together with the antipyretics, will generally succeed in stopping the convulsions. Ergot has been especially recommended by Althaus. He uses Bonjean's ergotine in watery solution (Julius Althaus: "On Infantile Paralysis," London, 1878, p. 51). The dose varies according to age under five years; from 0.01 to 0.02 gm. is injected once or twice a day. The treatment is continued until the temperature has become normal.

During the paralytic stage of the affection the treatment is well understood. Here the indications are, first, to treat the myelitis and thus promote and aid the regression of the paralysis; second, to treat the paralysis.

For the inflammation in the cord we can do but little. Ergot is given with supposed benefit. But the natural course of the inflammatory process is to destroy the ganglion cells in the gray anterior horns; when this has taken place, it is difficult to conceive how any internal medication can restore the destroyed nerve elements. It is claimed, however, and perhaps with some propriety, that those portions of gray matter which are only the seat of congestion can be benefited by internal medication; hence the ergot. With the same object in view counter-irritants to the spine are also used, such as iodine painted externally, blisters and cupping, either wet or dry. Dry cups applied to the spine on a level with the supposed lesion are better than wet cups. For obvious reasons they are also better than blisters.

Electricity is the curative agent in this affection. It may be applied locally to the spine, and also to the paralyzed muscles. Both galvanism and faradism are recommended. In my opinion, however, galvanism is more rational in theory and more effective in practice. Central galvanization of the spine is performed by placing one large flat electrode over the site of the lesion and the other over the farther extremity of the spinal column. An ascending (irritating) current should be employed, of strength sufficient to be felt by the patient; generally from twelve to sixteen elements Leclanché are sufficient. The duration of the applications should not exceed five minutes, and they should be repeated once every second day.

The application of electricity locally to the paralyzed muscles is the most effective use of this agent in this disease. Under the head of deformities we have already discussed its importance as a diagnostic agent. By the use of faradism alone we can recognize whether a patient has been the subject of a spinal-cord or peripheral-nerve lesion, or of a cerebral lesion. In advanced cases of atrophy from this disease the reaction to faradism is entirely destroyed; in these cases, therefore, the application of faradism as a therapeutic agent is certainly useless. I never apply this current until the muscles have sufficiently recovered to show a slight reaction when it is applied. Very few muscles, however—with the exception of those which are entirely destroyed—lose their excitability to galvanism, although the reaction present is generally that of degeneration. Galvanism, therefore, applied to the paralyzed muscles and nerves, causes both to become excited. This stimulus is undoubtedly beneficial, and persevering treatment with galvanism, continued for months and even years, is frequently successful in restoring muscles that were hopeless, to all appearances, when the treatment began. I apply the current by the aid of the interrupting electrode to the paralyzed muscles, and the other pole, generally the cathode, to some indifferent point. Applications to a limb should not exceed three minutes in duration.

Treatment of Deformities.—The principal therapeutic means at our command in the treatment of the deformities are tenotomy and mechanical appliances. Under the latter head I also include massage.

It has long been a question whether it is permissible to cut the tendons of the contractured muscles, and thus virtually paralyze all of the remaining healthy muscles of the limb. But, as is often the case, we find here that what would theoretically appear to be unwarranted, is found, in practice, to be sound and proper treatment. Careful consideration will show that the above objection is only apparently valid. Tenotomy disables a muscle only for a short time. The tendon soon reunites and the muscle is enabled to perform its functions to far better advantage than before. The strained position of the limb is relieved and the patient is enabled to use a joint which was entirely disabled before tenotomy was performed. Conservative surgeons prefer to stretch a contractured tendon, provided it admits of stretching. But such stretching, unless maintained for a very long period, is apt to be of but temporary utility; for a relapse is sure to occur when extension has been remitted. Where time, then, is important, tenotomy is certainly preferable to extension. I do not believe that the argument that tenotomy weakens a muscle is tenable. The active portion of a muscle is certainly not the tendon, but the muscular fibre. Tenotomy results in lengthening the tendon, the muscular fibres retaining their integrity. If healing has been properly looked to, the united tendon will not stretch more than is proper for the restoration of the joint to its proper function. Where, however, the contracture is yielding, traction will readily accomplish all that is necessary, and should be preferred to tenotomy. It will be impossible, in the limits of this article, to describe all of the instruments used for purposes of extension of different muscles. For talipes equinus I know none better than Dr. Shaffer's "extension shoe," the working of which has been thoroughly described in a paper read before the Academy of Medicine. For varus, Dr. Shaffer has devised an equally effective "lateral extension shoe." In calcaneus the chief indication is to raise the heel, the contracture rarely requiring extension or tenotomy. For these cases, as in all cases of paralytic club-foot, the shoe that is worn daily should have inside, covering the sole, a steel plate, to keep the sole firm and to prevent the shoe yielding itself to the deformed position of the foot. If the case be one of equinus, the heel should be fixed to the sole of the shoe by means of a strap passing over the instep. In all cases the shoe should be laced and made so as to open to the toes. The paralyzed muscles in many of these cases can be replaced, to a certain extent, by properly applied elastic straps, to act as artificial muscles. Contracture at the knee-joint should be overcome by tenotomy or extension. If the muscles about the knee-joint do not retain sufficient power to enable the patient to stand or walk with some firmness, we can virtually ankylose this joint by an apparatus in which a rigid bar passes from the hip or thigh down to the foot, without a movable joint at the knee; or a joint may be made at the knee, which, being guarded by an automatic spring, becomes rigid as soon as the patient assumes the standing position. One important principle in the application of apparatus for these deformities must not be lost sight of, and that is, that all apparatus must be so attached to the limb or body that the healthy muscles may be able to control or carry it, while it aids and takes the place of the paralyzed member. On the mechanical treatment of lateral curvature we will say nothing, the field being too large for the limits of this article. In treating the deformities of the upper arm and hand the principles already laid down will serve as a guide.

In the final stages of the disease, when contracture and paralysis have destroyed the function of limbs, and flail joints have rendered utterly useless whole extremities, certain surgical procedures will benefit the patient very greatly. Thus a healthy contractured muscle, which is useless owing to paralysis of its opponent, may have its tendon implanted at or near the insertion of the paralyzed muscle, and thus to a certain extent be enabled to perform the function of that muscle. This operation, known as tendon grafting, was first performed with good result by Nicolodoni in 1882. Goldthwait, of Boston, in 1896 reported a series of very interesting cases of this type. Arthrodesis has been useful in converting a flail leg into an efficient prop, much superior to a splint. Such ankylosis of joints is useful in bringing a useless joint into better position than that in which it has been left by the paralysis and resulting contractures.

Acute Poliomyelitis Anterior in Adults.

There is no doubt that a condition resembling, in its course and symptomatology, the same disease as it occurs in children may affect adults, although far more rarely than children. This has been evident from cases reported since that of Moritz Meyer in 1872 ("Die Electricität in ihrer Anwendung auf praktische Medicin," 2te Auflage, 1861) to the present time. Many of the cases reported as cases of acute poliomyelitis anterior in adults were in reality cases of polyneuritis without sensory symptoms. Indeed, a multiple neuritis of anterior spinal nerve roots would produce a condition simulating poliomyelitis anterior acuta in its symptomatology almost perfectly. The adults in whom this disease may occur are rarely more than thirty years of age. The disease is apt to affect adults who have recovered from an acute infectious disease, such as measles and scarlet fever. One case was reported as following an attack of rheumatism. Another case was supposed to be due to an exposure to cold after active physical exercise. The adult cases occur far more rarely than the infantile cases.

The symptomatology is almost identical with the same disease in children. Pain in the limbs preceding the occurrence of the paralysis is a symptom which has been reported in most of the cases. This pain disappears as soon as the paralysis occurs. The paralysis has the characteristics described in discussing infantile spinal paralysis. Its distribution in adults is characterized by the same lack of uniformity as in children. It is regressive. In adults, however, complete spontaneous recovery is believed to be possible. There is absence of patellar reflex. There are no sensory disturbances except the temporary pain just referred to. One or more muscles, groups of muscles, or extremities may be involved. There is sometimes backache. There are no motor disturbances of the rectum or bladder. Atrophies and degenerations occur as in the same disease in children. Similar electrical manifestations can be demonstrated in the paralyzed muscles. The reactions to galvanism and faradism are the same as in the infantile form of the disease. Deformities are not so apt to occur as a result of contractures in paralyzed muscles and their opponents, owing to absence of the factor of growth, which has such an important influence in disturbing the equilibrium between the healthy and paralyzed muscles of an extremity in young children suffering from this form of paralysis.

The diagnosis of this affection in adults is difficult, because the paralysis of poliomyelitis anterior acuta resembles that due to other pathological lesions to which adults are more often liable. Polyneuritis has already been mentioned. However, fever, followed by a rapidly developing motor paralysis, acute in its onset, which when it has reached its height begins to improve, together with the characteristic electrical symptoms, should enable the physician to make a diagnosis, at least as soon as the fever has subsided and the paralysis has become stationary.

The pathology of this disease in adults is the same as when it occurs in children.

The treatment is that which we have indicated in the same condition when it occurs in children, both in the stage of onset and in the chronic stage.

Poliomyelitis Anterior Subacuta et Chronica.

This form of poliomyelitis anterior is also generally found in adults; it is very rare. The condition resembles multiple neuritis in its symptomatology in a general way, and doubtless most of the cases reported clinically as poliomyelitis anterior subacuta were in reality cases of multiple neuritis. Yet cases have been reported in which post-mortem findings demonstrate that subacute or chronic poliomyelitis anterior is an actual entity, although a rare condition.

As etiological factors we find first metallic poisoning. In these cases this condition may be present alone or it may be accompanied by a toxic neuritis of peripheral nerves. The condition has also been seen during pregnancy. One case reported gave a history of an attack of infantile paralysis during infancy, followed in adult age by a gradually developing chronic poliomyelitis.

Pathologically the findings are similar to those in poliomyelitis anterior acuta, which have been recounted in the earlier portion of this article. Some of these cases, however, while they show degenerative changes with atrophy and sclerosis of the gray anterior horns, show also degenerations in the crossed pyramidal tracts and anterior nerve roots. One case reported by Oppenheim also showed systematic degeneration of the columns of Burdach in the cervical and dorsal regions, together with atrophy of the posterior nerve roots. One case has even shown an extension of the process to the columns of Clarke, and the posterior horns were also slightly involved, in addition to the changes in the anterior horns.

The root of the hypoglossus has also been found involved.

The atrophic changes in the peripheral muscles and nerves, as well as those occurring in the bones, while less marked, are similar to those found in poliomyelitis of children.

The symptoms are as follows: A paresis developing with a paralysis of a single limb or muscle is followed, in a week or month or year, by a gradually developing paresis or paralysis of another limb or of other limbs. This gradually extending, paralysis may continue, at intervals of longer or shorter periods, to involve more muscles until a large portion of the voluntary muscular system is affected, although one case has been reported in which there were bulbar symptoms. The muscles that are the seat of the paralysis gradually undergo atrophy, and give the complete and partial degeneration reaction found in poliomyelitis anterior acuta. The paralysis keeps extending for a year or more, and then may become stationary for the remainder of the life of the patient. In this form of the disease, unlike the acute form, there is observed little or no spontaneous improvement in the paralysis, while in infantile paralysis it is the rule that the paralyzed muscles recover, to a greater or less extent, spontaneously shortly after (*i.e.*, a few days or weeks after) the paralysis has set in. In the subacute and chronic form of the disease there is no spontaneous improvement.

Death generally occurs through some intercurrent disease, such as pneumonia, or, in rare cases, by paralysis of the nerves of respiration.

The differential diagnosis rests upon the absence of bladder and rectal symptoms. The diminished or lost patellar reflex; the absence, with rare exceptions, of sensory symptoms; the atrophy of the paralyzed muscles and limbs, are also important symptoms of the disease.

Progressive muscular atrophy can be differentiated from this condition by the fact that the paralysis in poliomyelitis subacuta and chronica precedes the atrophy, while in progressive muscular atrophy the atrophy precedes the paralysis. From multiple neuritis the condition is distinguished by the absence of sensory symptoms both subjective and objective. From amyotrophic lateral sclerosis it can be distinguished by the absence of the contractures and exalted patellar reflex which is characteristic of this affection.

The treatment consists of electricity, massage, baths, orthopædic apparatus, and drugs. The rules laid down, under acute infantile paralysis, for the employment of these agents in the treatment of the disease hold good here.

Orthopædic apparatus should be so constructed as to give rest and firmness to the paralyzed limb, by fixation of incompetent joints, etc., and to cause healthy muscles and limbs to do the work of those that have been paralyzed. Of the drugs that may be used, intramuscular injections of strychnine are the best. Galvanism is the form of electricity most applicable It should be used in accordance with the directions already laid down.

SPINAL-CORD DISEASES: SPINAL HEMIPLEGIA.

(Synonym: Brown-Séquard's Paralysis.)—This term is applied to a group of symptoms produced by disease or injury of a lateral half of the transverse section of the cord. The array of symptoms to be mentioned become more or less clearly defined according to whether the entire half-section of the cord is affected or only a part thereof. The clinical picture was first described by Brown-Séquard, the description being based upon the results of experiments on animals as well as upon clinical and pathological observations in man. The conclusions of Brown-Séquard have not always been accepted, but Oppenheim has recently called special attention to the fact that, while experimental investigations have varied greatly in their results, accumulated clinical experience altogether upholds the clinical picture which he described.

Briefly stated, the result of lesion of one-half of the cord is motor paralysis of one-half the body below the seat of, and on the same side as, the lesion, and loss of sensation to a corresponding extent on the other side. *The motor paralysis is on the side of the lesion, the sensory paralysis is on the opposite side.* The extent of the paralysis depends on the height of the lesion; if it is in the cervical region, the upper extremity as well as the trunk and lower extremity is affected; if it is at a lower level, the manifestations will be limited to a corresponding part of the body. If the lesion be in the lower lumbar or sacral region, the motor and sensory symptoms will be on the same side, for at this level the sensory fibres have not yet crossed over to the other side of the cord.

The anæsthesia of the opposite side does not involve all qualities of sensation. The senses of pain and temperature are chiefly affected. In well-marked cases these do not escape. Tactile sensation is often unaffected, and, when impaired, is affected about as often on the side of the lesion as on the opposite side. On the other hand, the muscular sense is always impaired on the paralyzed side, that is, on the side of the lesion. Another symptom allied to the latter, ataxia, is often found on the same side when the motor paralysis is slight or when it has begun to improve.

Another notable sensory symptom is hyperæsthesia on the side of the lesion, that is, the side of motor paralysis. In well-marked cases this is nearly always present, though it may be slight in degree. This area of hyperæsthesia is often bordered above by a narrow zone of anæsthesia, the latter due to injury of the posterior spinal roots on the same side. On the other hand, injury of the anterior spinal roots (also of the anterior cornua) may be the cause of atrophy of the paralyzed muscles corresponding to the level of the lesion. Otherwise the paralysis usually assumes a spastic form with increased tendon reflexes and the appearance of the Babinsky phenomenon.

Not infrequently there is, temporarily, vaso-motor paralysis with some elevation of temperature on the side of the lesion. According to the seat of the lesion there may be vesical, rectal, or oculo-pupillary symptoms. Trophic symptoms have been observed in a few instances, sometimes on the side of the lesion, sometimes on the opposite side.

To recapitulate: The symptoms on the side of the lesion are motor paralysis, loss of muscular sense, and hyperæsthesia; on the opposite side, loss or impairment of the sense of pain and the sense of temperature. Tactile sensation is as likely to be affected on the one side as on the other, and, at least in old cases, more likely not to be affected at all. Temporary vaso-motor paralysis, and, very frequently, ataxia are found on the side of the lesion.

The physiological explanation of the symptoms is as follows: The motor fibres in the cord are in the antero-lateral column on the same side as the muscles with which they are in relation, their decussation occurring at a higher level, viz., in the medulla. The nerve fibres for muscular sense are in the posterior column, also on the same side, their decussation not occurring until they have reached the brain. On the other hand, the fibres which convey the sense of pain and that of temperature enter the cord through the posterior root and then pass in one of the commissures to the other side, ascending in the opposite antero-lateral column (it is generally believed in Gowers' column) to the brain. There is much greater uncertainty as to the paths for tactile sensation. Mann believes, and Oppenheim accepts this theory, that any nerve fibres which convey centripetal impulses—that is, impulses from the periphery toward the brain—may convey tactile sensations, though they are commonly conveyed by paths in the posterior columns. This theory readily explains the varying conditions of tactile sensation in these cases. The ataxia is probably due to lesion of the posterior column. The hyperæsthesia has as yet not been very satisfactorily explained.

The lesions producing this array of symptoms are often of traumatic origin, such as gunshot wounds, or wounds with sharp instruments. The lesions due to disease are most frequently those of spinal syphilis. In some instances hemorrhage limited to one side, in others pressure or destructive effects of a tumor, again a circumscribed myelitis or sclerosis, etc., may be the cause of the clinical picture. In some of these instances, especially those of trauma and hemorrhage, the early symptoms are much more marked than the later ones. The vaso-motor paralysis is usually but transient. The motor paralysis is likely to improve. The paralysis that remains is usually of the flexors of the hip and knee and of the dorsal flexors of the foot. Ataxia is likely to appear as the paralysis disappears. If tactile anæsthesia exists it is also usually an early symptom, disappearing at a later period. The disappearance of symptoms is in part due to the absorption of effusions and exudations and lessening of pressure, in part perhaps to functions assumed by the other half of the cord, or even to healing and resumption of functions of affected nervous tissues.

In cases of progressive lesions we may find double Brown-Séquard paralysis—first the symptoms of lesion of one-half of the cord, and then those due to the extension of the lesion to the other side. *Philip Zenner.*

SPINAL-CORD DISEASES: SYRINGOMYELIA.—It is impossible to give a satisfactory definition of a disease with such protean symptomatology and diversity of pathological findings. In general the name is given to a process of new growth in the gray substance, or to intramedullary cavities of varied origin, marked clinically by disturbances of motor, sensory, and trophic nature; by frequent bulbar symptoms, by almost constant reflex changes; usually by extreme chronicity. Reports of cavity formation in the spinal cord date back to a description of Étienne in 1564. Morgagni and Santorini recounted a case in 1740. Numbers of descriptions date from the early part of the last century. Calmeil in 1828 pointed out the influence of developmental anomalies. Ollivier first used the term "syringomyelia," though his conception of the cavity-formation needed later correction. A little later it was recognized that the pathological condition syringomyelia not infrequently was associated, clinically, with muscle atrophies (Landau, Nonat, Lenhossék, Gull). This association did not escape the acumen of Duchenne de Boulogne: "I found in a good part of my cases that electrocutaneous as well as ordinary cutaneous sensibility was affected. This anæsthesia is often so marked that the patient does not feel the strongest current or the ferrum candens."

Up to the publications of Kahler and Schultze in 1882 few clinical facts had been collected, but anatomical views had become sifted and well formulated. Five chief views maintained that the cavities resulted from: (1) a dilated central canal (Stilling, Waldeyer); (2) retrogressive changes in foci of chronic myelitis (Hallopeau, Charcot, Joffroy); (3) molecular degeneration due to vascular changes (Lockhart Clarke); (4) destructive metamorphosis of tumor masses (Grimm, Simon, Schultze); (5) certain developmental anomalies (Virchow, Leyden). In 1882 simultaneous publications of Kahler and Schultze quickened clinical interest and formulated rules of diagnosis. Since then the literature has become immense, the magnificent monograph of Schlesinger in 1901 represents the sum of our knowledge of the disease and has been freely drawn upon in the preparation of this article.

Pathological Anatomy.—The cord may be hard to remove on account of marked kyphoscoliosis. There may be pachymeningitis, or pia or nerve-root thickening. The cord may seem flat and thin, the medulla small; or it may appear swollen in certain regions, especially in the neighborhood of the cervical enlargement; on section there may be cavities varying greatly in shape, vertical extent, and diameter. Frequently there are no macroscopical cavities, but irregular reddish-gray tumors in the gray substance. The medulla oblongata is often involved in the tumor- or the cavity-formation. The process may be limited to one side or to a small part of the cord; or it may extend throughout the cord and medulla oblongata. Usually the formation of tumors or of cavities involves the gray substance about the central canal. The anterior commissure is most often intact. One or both posterior horns may be attacked, or the ventral portion of the posterior columns; if the destruction advances, a large part of the gray matter disappears and the whole of the posterior and a large portion of the lateral columns become involved. The cavity walls may be smooth or ragged, may be lined by ependyma or closed by a proliferation of the glia. There may be evidence of old hemorrhage. As a rule, all changes are most marked in the cervical cord.

Microscopically, the tumor masses consist of glia cells and fibrils. The cavities are lined by a firm membrane that at times shows an epithelial covering. The tumors spring from the central part of the cord, the posterior horns, the posterior commissure, etc., and spread through the gray substance toward the posterior columns along the posterior median septum. The ultimate cause of the growth is to be sought for in certain developmental anomalies of the central canal or of the glia. The central canal may be unduly large or markedly irregular with diverticula. It may fail properly to develop and be marked by persistence of the dorsal process which is a characteristic at a certain stage of fœtal growth; or this diverticulum may be cut off and may persist as a dorsal canal seemingly independent of the central canal (Leyden). At other times nests of embryonic glia cells (ependyma) lie scattered in the neighborhood of the central canal or along the dorsal line of closure about the posterior median septum; and these may spontaneously, or under influence of some irritation (trauma), begin to proliferate and give rise to the glia tumors or gliosis (Hoffman). The cavity-formation may depend on many different processes—on dilatation or diverticula of the central canal, softening after trauma, hemorrhage or inflammation, destruction of tumor masses, retrogressive changes in glia proliferations (the common syringomyelia). But cavities and cysts after hemorrhage, myelitis, disintegration due to trauma, are rarely to be reckoned with the changes known as syringomyelia; they are stationary and not progressive. Another element is necessary, viz., some congenital disposition of the cord—an inherent tendency of the ependyma or glia cells to proliferate. Developmental anomalies of the whole central nervous system or only of the central canal and its neighborhood are found, therefore, in most cases of syringomyelia; anomalies of vessels and of the vascular connective tissues are also common and contribute to further proliferation and later cavity-formation.

Next to the posterior horns and posterior commissure the anterior horns and the posterior columns are the parts of the cord most affected. The cells of the anterior horns are either directly invaded by the gliosis, or are destroyed by hemorrhage, or at times they undergo atrophy at a distance from the process—perhaps as a result of inherent weakness. The ventral portion of the posterior columns—the ventral field of the posterior columns; the dorso-medial sacral bundle of Obersteiner; Schultze's comma tract—most frequently suffers. The pyramidal tracts may either be directly invaded or they may undergo degeneration from pressure of the growth at a higher level of the cord.

Bulbar Lesions.—Pathological changes occur in the median line or laterally, especially along the entering vagus roots. The cavities are as a rule small—mere slits rather than holes. Those lying near the median line are due to developmental anomalies, while the lateral rifts and cavities have their origin in vascular changes, in inflammatory processes. The cavities are lined with glia, but usually there is no distinct evidence of proliferation. The vessels are enlarged and present in unusual number. The central cavity when present is lined with ependyma. The lateral lesions may involve the nerves from the twelfth to the fifth; the twelfth, tenth, ninth, and descending roots of the fifth are most often implicated. The process ends at the pons. The fillet is frequently destroyed. The process is nearly always predominantly unilateral.

In judging of pathological findings one must remember the possibility of various artefacts. Tears may occur along the posterior horn and commissure and in the gray substance from pressure and crushing during removal of the cord (Kolisko). Cavities may result from putrefactive gas-formation, and changes may go on in the specimen while it remains in the hardening fluid if this is not frequently changed during the first days. Van Gieson has called attention to the various artefacts in an exhaustive article.

Etiology.—Not infrequently the disease seems to have direct relation with trauma of some sort. According to Minor a central hæmatomyelia due to trauma is often the starting-point of the abnormal process. Perhaps hemorrhages due to trauma during birth act in the same way (Schultze). It is plausible to think that, in the case of the developmental anomalies described above, the incitement to glia proliferation may be given by trauma; experimental evidence favors such a view (Schmaus). The theory has been advanced that even peripheral trauma or a panaritium, etc., may, with the predisposition already mentioned, and through the agency of an ascending neuritis, be able to start the process of proliferation; this supposition has little probability. Different infections, especially typhoid and influenza, may act like trauma in certain cases and supply the initial irritation leading to later tumor-growth. Excessive temperature changes, particularly exposure to cold, seem occasionally to act in the same way. Syphilis may lead to cavity-formation through vascular and meningeal lesions, but has little influence in the production of the progressive changes which characterize syringomyelia. Leprosy plays no rôle as a causal factor. The relations of trauma to the disease are most important from a medico legal standpoint. Most often the trauma is an accident in the already developed disease. Rarely, in congenitally predisposed subjects, it may be the primal cause of the process. Not infrequently it leads to decided exacerbation of the quiescent disease. Most often its effects are disastrous, due to peculiarities of the disease and not to severity of the trauma (trophic joints, spontaneous fractures, etc.).

Symptomatology.—From the character of the pathological lesions it is plain that symptoms must be protean and capable of almost endless combination. In the most usual localization of the process in the cervical enlargement the picture is fairly typical. Lightning pains in one or both arms, or paræsthesiæ, especially sensations of burning or coldness, or "burning cold," not infrequently precede striking changes. Atrophy of hand or arm muscles is a marked feature; it may be unilateral. The small hand muscles are most often involved; the process may begin in the shoulder group. Usually when atrophy is well marked, sensory changes can be demonstrated. These at first are found over small areas of the hands, arms, or shoulders, and there may be only a moderate diminution of temperature perception, not a complete loss. Vaso-motor disturbances and trophic changes of varied kind may be noted in the skin, subcutaneous tissues, bones, and joints. The knee-jerks are increased; if the process involves one arm predominantly the knee-jerk on the same side will be the livelier. Later on, contractures may occur; the atrophy progresses; unilateral bulbar symptoms may develop; spastic paraplegia becomes marked; further trophic changes are seen; sensory changes cover wide areas and increase in intensity; the sphincters may be affected.

If the cavity-formation involves the dorsal and lumbar cord, pain and paræsthesiæ will be felt in corresponding nerve roots. The muscle-atrophy will affect the adductors, quadriceps extensor, peroneus group, the back extensors, perhaps the glutei and other muscles of the calves. The knee and Achilles reflexes are usually increased. Sensory and trophic disturbances are found in the lower extremities or in the trunk. The sphincters are frequently affected.

When the lumbo-sacral cord is involved there is atrophy of the glutei, knee flexors or foot muscles—often unilateral. Sensory changes are demonstrated in the feet, perineum, bladder. The sphincters are usually affected early, but they may escape. Trophic changes are often peculiar. The leg and foot may remain small or may be unduly large; bone and joint changes, panaritium, malum perforans, are frequent. The patellar as well as the Achilles jerks are usually increased; a weighty sign is loss of the Achilles reflexes with normal knee-jerk.

Association with congenital hydrocephalus or spinal deformities, spina bifida, are common.

Symptoms in Detail.—1. *Sensory Disturbances.*—The essential characteristics of the sensory changes were well described in the first publications of Kahler and Schultze. Laehr, Hahn, Dejerine, Brissaud, Schlesinger, and von Soelder have studied in detail the peculiarities of distribution. Most characteristic is the so-called "syringomyelia dissociation"—the essential preservation of touch and sense of pressure, position, and movement, and more or less complete loss of the sense of pain and the temperature sense. At times only the temperature sense is involved or the perception of heat may be lost and that of cold preserved, or *vice versa*. At times only extremes of temperature are confused and moderate degrees are well recognized (Dejerine). The distribution of the sensory loss follows the rules of segmental innervation (Laehr) in nearly all cases; in the extremities the loss is in bands folllowing the axis of the limb; over the trunk the changes occur in zones about the body. Even in the trigeminus the segmental type prevails (von Soelder). In certain cases, however, the so-called "geometrical" distribution of Charcot holds good; the analgesia or thermanæsthesia affects an entire hand, or the entire arm, or the arm and part of the trunk, etc.—"sleeve," "cuff" "waistcoat," forms of Charcot. This form exists without complicating hysteria (Brissaud, Schlesinger). Even within these plaques Laehr has demonstrated a tendency to segmental distribution of varying degrees of analgesia or thermanæsthesia.

In many cases tactile sensibility is normal, in others there are losses over small areas. Deep sensation may at times be involved, owing to the existence of posterior column lesions. Ataxia is not infrequent. Stereognosis is often affected. Surface sensation and deep sensation are not necessarily affected to an equal degree; there may be loss of pain in deep structures, as bones and joints, while the skin sensations over these parts may be normal; usually, however, they are involved simultaneously. Frequently there is loss of testicular pain on pressure. The mucous membranes are commonly involved.

Pain is common and often severe; it may be constant, boring, not infrequently lancinating; it is felt oftenest in the arms and upper trunk; with high seat of the lesion there may be occipital neuralgia or obstinate pain in the distribution of the trigeminus. Paræsthesiæ are usually present, often a feeling of cold or heat, or a mixed sensation of "burning cold." The pains and paræsthesiæ may persist in regions in which there is objective loss of sensation. The subjective sensations are important in diagnosis as they appear early and often call attention to atrophy and objective sensory changes. The paræsthesiæ of the temperature sense may be extreme and may lead to grave injury through the patient's ungoverned use of counteracting heat or cold. Analgesia and thermanæsthesia depend on lesions of the central gray matter and adjacent conducting paths. It must be remembered that dissociation of sensory qualities may not be an attribute of syringomyelia alone; it is frequent in hysteria and may occur in brain or spinal-cord lesions or in affections of peripheral nerves.

II. *Motor Phenomena.*—Atrophy is the symptom of chief import. It involves the arms most frequently, is often unilateral. The small muscles of the hand are most constantly affected. In early stages there may be the type of a peripheral median or ulnar lesion, manifesting itself in the form of the ape hand or the claw hand; combinations of the two are not infrequent. More frequent is the simultaneous atrophy of all the small hand muscles, the Aran-Duchenne type. The process may skip the forearm and spring to the shoulder group. At times all muscles undergo extreme wasting. The shoulder muscles may be attacked first; frequently individual bundles undergo atrophy, while others remain normal or become hypertrophied. The lower third of the trapezius is commonly involved, the upper part very rarely. The process is seldom symmetrical. The thorax muscles may be involved irregularly—primarily or after the arms. The intercostal muscles and diaphragm are usually spared. The lower extremities, as a rule, follow the arms in point of time. The quadriceps and other muscles of the calf of the leg (foot extensors) are the common seats of atrophy. Various forms of club-foot occur. At times atrophy is masked by fat or diffuse œdema.

Fibrillary twitching is frequent; it may be an early symptom and is often felt by the patient. Tremor, choreiform twitching, and other spontaneous movements occur; they may or may not be limited to atrophic muscles, and are often associated with paræsthesiæ or pain. Tonic cramps occur most often in the lower extremities, but they may involve many muscles and simulate at times hysterical seizures. Gradations toward myotonia have been observed, muscles becoming rigid on exposure to cold. The myotonic reaction has been observed. Contractures are frequent in later stages and may lead to great distortion. The gait shows usually a spastic paraplegia; ataxia is not infrequent; cerebellar gait is rare. All forms of electric reactions may be demonstrated. Often there is only quantitative loss; at times the reaction of degeneration may be found in separate muscle bundles; at times complete reaction of degeneration is present.

III. *Trophic Changes.*—The manifold trophic disturbances of syringomyelia speak rather for separate trophic nerves and centres. Trophic changes may exist without demonstrable loss of sensation. It is difficult to classify the diverse skin lesions that may occur. Peculiarities of sweat secretion are common: hyperidrosis, anidrosis, unilateral or regional sweating, sweating in response to cold and not to heat. Hyperidrosis may be an early symptom, its distribution may correspond to the sensory changes.

Scars of injuries and burns, panaritium (often painless), eczema and deep fissures, blisters, erythema, urticaria, and pemphigus are frequently seen.

Thickening of the skin of the palms and of the fingers may be extreme. Firm œdema of the hands and the peculiar thickening of the hands—the *main succulente* of Marinesco—are not uncommon.

Scleroderma has been noted in a few cases; Raynaud's symptom-complex is rare, gangrene not uncommon. Bedsores may develop in acute cases. Keloid is common. The nails are often thick, brittle, and deformed. Aside from the presence of a tuft of hair over a spina bifida or a spina bifida occulta, an overgrowth of hair rarely occurs.

Joint lesions are most important. They may be the earliest symptom; eighty per cent. affect the upper extremities. Pain may be a prodrome, but usually the developed affection is painless—a striking feature. The change in the joint may come on suddenly, with large effusion or with marked deformity and grating. The changes are due to trophic and not to mere mechanical influences. Atrophic and hypertrophic forms occur. Extreme deformity may result. The finger, elbow, and shoulder joints are the usual seats of trophic change. The lower extremities are more rarely involved. Exostoses about the joints and ossification of muscles are not infrequent. Suppuration may occur. The lesions develop spontaneously or under the influence of trauma, which may be slight.

Fractures of bones may occur spontaneously or with insufficient cause. There is a great preponderance of forearm fractures. Healing may be long delayed and incomplete. Exostoses may form. At times there is overgrowth of the bones as a whole or enlargement of an entire extremity, or of the hand or foot. Usually the enlargements are partial and irregular. They may develop quickly and be associated with inflammation. Hitzig described a case with unilateral bulbar lesions and hypertrophy of the face on the same side. I have seen great enlargement of an arm due to recurrent lymphangitis from panaritium infection.

Two cases of spontaneous tendon rupture have come under my observation: in one there was rupture of the long head of the biceps of the right (affected) arm; in the other, rupture of the patellar tendon in a lumbo-sacral type of the disease.

Thorax Deformities.—Bernhardt was the first to call attention to the frequency of scoliosis and kyphoscoliosis. Scoliosis is important as a symptom; it may occur early and independently of muscle weakness. The kyphoscoliosis occasionally leads to great deformity. It is most frequent in the dorsal region. Sometimes there is great tenderness of the spine, which may be limited to the extent of the deformity or of the process within the cord. Oppenheim regards the scoliosis as a congenital anomaly in certain cases.

Spina bifida and spina bifida occulta are not uncommon.

The *thorax en bateau* is the name given by Marie to a peculiar depression of the upper part of the sternum; it is often associated with subluxation of the clavicles forward.

Hemiatrophy of the face has been reported and may or may not be associated with lesions of the sympathetic.

In this connection may be mentioned the peculiar irregular or "crooked" look of many patients afflicted with syringomyelia. This seems to depend on irregularities of head, face, and thorax, on irregular thickening of soft parts, and on irregular innervation of facial muscles. It is important as emphasizing the influence of congenital anomalies in the pathogenesis of the disease.

IV. *Reflexes.*—The arm reflexes are often absent, and when present they follow the atrophy or the affections of the joints. Increased knee-jerks form a cardinal symptom. Clonus is frequent; unilateral increase is common; even with lumbo-sacral localization the knee-jerk is curiously persistent and usually increased. Absent knee-jerk is found in association with tabes or nerve-root lesions or destruction of lumbar centres. The superficial reflexes are not often absent; abdominal and cremaster reflexes are frequently increased. The Babinski reflex is not constant; its absence is not against syringomyelia, even when there are marked spastic symptoms.

V. *Sphincter Disturbances.*—The bladder is not generally affected early and may never be involved. Sensibility of the mucous membrane may be lost and yet the function be perfect. Difficulty of starting the urine is the usual symptom in the beginning; later there may be incontinence. Diabetes may occur in bulbar lesions. Pollakiuria is frequent and may be bothersome.

Constipation is common, but incontinence of the bowels is rare. Sexual and menstrual troubles are very rare.

VI. *Bulbar and Cranial Symptoms.*—As was stated in the previous description, the anatomical process may involve nerves from the fifth to the twelfth; other cranial nerves may be influenced indirectly by hydrocephalus, tabes, etc. Symptoms on the part of the olfactorius and auditory nerves are very rare.

Taste may be affected, but complicating hysteria may be a cause; the affection is usually unilateral.

Eye symptoms are important. Neuritis and atrophy of the nerve are rare occurrences and probably depend on hydrocephalus or actual gliomata. The pupils are often different on account of lesions of the sympathetic. The narrow pupil and narrowed opening between the eyelids, as well as the retrocession of the bulb, are found on the side chiefly affected. Kocher has shown that lesions of the medulla and upper cervical segments are as competent to produce sympathetic disturbances as are lesions of the lower cervical and first dorsal segments.

Argyll-Robertson pupils do not belong to syringomyelia; if present, they suggest complicating tabes.

Nystagmus occurs more frequently than in any other nerve lesion except multiple sclerosis.

Eye-muscle palsies may occur, but, on the whole, they are rare. They may be recurrent; the abducens is most often affected.

Trigeminus lesions are important. Violent neuralgias or paræsthesiæ may be the first symptom. Dissociation of sensation is usual, and the distribution follows segmental types. The "parietal-ear-chin" line of Kocher marks the upper level of the second cervical segment supply. As the proximal trigeminus becomes involved the first sensory loss is in the scalp and then in areas narrowing concentrically toward the nose (von Soelder, Schlesinger).

The motor fifth is hardly ever affected. The corneal reflex is very rarely absent. Occasional trophic disturbances occur, such as loss of hair or teeth; or the tears may be more abundant on the affected side. Implication of the facial is uncommon; most often the lower portion is alone affected. Often there is no reaction of degeneration.

Hemiatrophy of the tongue is a frequent and may be an initial symptom. Unilateral affections of the soft palate and larnyx are extremely important in diagnosis. In the larynx the usual lesion is paralysis of muscles supplied by one recurrent. Sensory and motor laryngeal changes may be independent of one another. It is important to remember that the laryngeal palsies may develop in an apoplectiform manner with marked vertigo and even loss of consciousness. Vertigo, however, may occur independently of bulbar lesions.

Vomiting may be periodic, occurring in attacks like regular tabetic crises. Heart symptoms are rare.

Headache is not a feature of the disease. Convulsions may rarely occur. Scanning speech has been reported in several cases.

Atypical Forms.—There may be, for long periods, the picture of a spastic paraplegia or an amyotrophic lateral sclerosis. Sensory changes may be absent for years (Bouchard). Bulbar symptoms may come on in an apoplectiform manner and for a long time they may be the only manifestations of the disease. In very rare cases there may be widespread sensory changes—anæsthesia as well as analgesia and thermanæsthesia. In the celebrated case of Spaeth and Schneppel there was practically total loss of all forms of sensation.

In 1883 Morvan published descriptions of a symptom-complex that has since been known by his name. He described the combination of painless panaritium of the fingers with great deformity and accompanied by marked loss of pain- and temperature-perception in the hands and arms. Autopsies of Joffroy-Achard, Prouff, Marinesco, Hoffman, Redlich, Schlesinger, and others have demonstrated the direct association of Morvan's symptom-complex with syringomyelia. On the other hand, the same picture may present itself in leprosy, and only a careful examination will enable one to make a differential diagnosis.

The early appearance of changes in the joints, spontaneous fractures, etc., can lead to confusion only on superficial examination.

Differential Diagnosis.—There is no doubt that syringomyelia represents a clinical if not an anatomical entity. Due attention to the combination of sensory, motor, and trophic changes will usually enable one to make a correct diagnosis. The following represent the chief conditions that may lead to confusion:

1. *Progressive Muscular Atrophy.*—Kahler and Schultze pointed out the importance of sensory changes in distinguishing syringomyelia from cases of muscle atrophy of the Aran-Duchenne type. The doubtful cases are those in which, for years, there are no sensory changes (Croeg, Dejerine). It is necessary to seek for isolated loss or diminution of temperature-perception. Increased knee-jerks, scoliosis, lesions of the sympathetic, trophic changes, paræsthesiæ, ataxia, sphincter disturbances, speak for syringomyelia.

2. *Amyotrophic Lateral Sclerosis.*—Sensory changes are rare, but they may occur (Oppenheim). Bladder symptoms, scoliosis, paræsthesiæ, unilateral bulbar symptoms, trigeminus involvement, nystagmus, are decisive for syringomyelia.

3. *Multiple Sclerosis.*—Tremor, nystagmus, scanning speech, increased knee-jerks, spastic paraplegia, ataxia, sphincter disturbances—these are symptoms that belong to both diseases. Some sensory change is not uncommon in multiple sclerosis, and even dissociation may occur (Freund, Reichel). Optic atrophy, especially atrophy of the temporal half, decides for multiple sclerosis. Marked sensory changes, muscle atrophy, trophic disturbances, scoliosis, speak for syringomyelia. Remissions may occur in either affection, but are more usual in multiple sclerosis.

4. *Progressive Muscular Dystrophy.*—If syringomyelia begins in the shoulder group of muscles atrophy is not rarely associated with partial hypertrophy, and, if cases of dystrophy are complicated with hysterical sensory changes, the two conditions will appear very much alike. Trophic disturbances, increased knee-jerks, segmental sensory distribution, bulbar symptoms, decide for syringomyelia.

5. *Meningomyelitis Luetica.*—Spastic paraplegia and dissociation of sensation may occur in both diseases. Brain symptoms and a Brown-Séquard type of motor and sensory lesions favor lues. Scoliosis and trophic changes are absent. Nystagmus is very rare.

6. *Tabes.*—There may be many symptoms in common. Strongly characteristic symptoms in either direction decide. Thus, for example, the Argyll-Robertson pupil, loss of knee-jerk, ataxia, sphincter disturbances, character of sensory loss, trophic changes in lower extremities, crises, belong to tabes; on the other hand, muscle atrophy, marked dissociation of sensation over large areas, increased knee-jerks, scoliosis, trophic changes in the arms, speak for syringomyelia.

7. *Hæmatomyelia.*—In this disease the symptoms are marked at first, but later some improvement takes place. Syringomyelia is usually steadily progressive.

8. *Plexus Affections.*—Cases have been reported of bilateral plexus palsies, of both the Erb and the Klumpke types. There may be dissociation of sensation as in syringomyelia, and the distribution may be of the segmental type. In some cases only continued observation will decide; as a rule, tenderness of the nerve trunks and of the spine is more marked in the plexus affections, there is no increase of knee-jerks, bulbar symptoms do not occur, and the losses of sensation are limited to the arms.

9. *Hysteria.*—Complications with hysteria may add to the difficulties of differential diagnosis in muscular dystrophies, atrophies, etc., as mentioned above; or hysteria may be added to or may simulate some of the symptoms of syringomyelia. In the sensory disturbances of hys-

teria dissociation is rarely segmental. Suggestion may lead to disappearance or transference of the sensory losses. Deep or superficial reflexes are little modified, trophic changes and atrophies are extremely rare. Bulbar changes do not occur.

10. *Central Tumors.*—(Tubercle gumma, glioma, etc.) Here symptoms are severe and advance quickly. Pain is severe; marked paræsthesiæ, especially of heat and cold, are usual; atrophies and paralyses, particularly paraplegia, come on rapidly. Ataxia and sphincter disturbances are frequent; there is often complete or partial development of the Brown-Séquard complex; if bulbar symptoms occur they are severe and run their course quickly.

11. *Pemphigus, scleroderma, Raynaud's disease, deformities due to arteriosclerosis, pellagra, and lathyrismus,* can rarely give rise to a confusion.

12. *Leprosy.*—The similarity between some forms of leprosy and syringomyelia was pointed out by Steudener in 1867 and by Langhans in 1875, but the publication of Morvan's work in 1883 first awakened general interest in the question. As described above, the Morvan symptom-complex was shown, by carefully made autopsies, to be associated with syringomyelia (Joffroy and Achard, Prouff, Redlich, Schlesinger, and others). But, subsequently, Zambaco published reports which showed that in Brittany, where Morvan had carried on his work and where leprosy was endemic, there occurred cases which merited the name of Morvan's disease, but in which the existence of leprous neuritis was absolutely proved. It is particularly these trophic forms of syringomyelia that are liable to be taken for leprosy, and it is equally true that the anæsthetic and not the tuberculous types of leprosy are confused with syringomyelia. Despite the views of some extremists, the two diseases are undoubtedly distinct. Leprosy has no influence in the production of syringomyelia, and unequivocal lesions of leprosy have never been found associated with syringomyelia; accidental combination may of course be possible. The leprous analgesia or thermo-anæsthesia depends on involvement of peripheral nerves and is usually not so widespread nor so segmentally distributed as in syringomyelia. Evidence of peripheral nerve disease is found in thickening of nerve trunks, particularly the ulna and great auricular. Bulbar lesions, increased knee-jerks, girdle sensation, sphincter disturbance, and scoliosis do not belong to the symptomatology of leprosy. On the other hand, the cutaneous nodes, widespread pemphigus, vitiligo, white scars, and, above all, the demonstration of bacilli in the blood, nasal secretion, etc., decide for leprosy. There are some cases, especially in districts where leprosy is endemic, in which a diagnosis is difficult; as autopsies prove, however, confounding of the two diseases can even then be avoided if a careful examination be made.

Course and Prognosis.—The disease is eminently chronic; cases have been known of thirty, forty, and fifty years' duration. The type of disease dependent on quick glia-proliferation (gliosis without cavity formation) runs a relatively rapid course (from three to six years), but the cases can hardly be separated clinically.

Intercurrent infections and trauma often influence the process unfavorably. Apoplectiform attacks may occur with accentuation of bulbar or spinal symptoms; marked remissions also occasionally occur. The bulbar lesions are on the whole benignant and may last for years unchanged.

Death may occur from bladder and kidney complications, from sepsis following the various trophic disturbances, and sometimes from bulbar lesions, but most often from intercurrent disease.

Treatment.—From the nature of the lesions it is impossible to expect direct results from treatment. In a few cases, due seemingly to lues, specific treatment has proved advantageous. Prophylactic measures play an important part. Such are: avoidance of trauma, of overuse of atrophic muscles; prevention of bedsores and, to a certain extent, of atrophic joints; avoidance of injury to analgesic extremities, and of exposure to injurious temperature changes; above all, great care in the avoidance of bladder complications.

Mud baths and gentle massage may help contractures.

Electricity, galvanic and static, may relieve pain or paræsthesiæ.

Panaritium and suppurating joints must be treated surgically; as a rule, wounds from surgical operations heal fairly. Pain may require phenacetin, antipyrin, pyramidon, salicylates, or morphine. Potassium iodide and mercury should be given in cases of questionable luetic origin, or iodide may be tried for a time in all cases. General tonics can only be of indirect service.

SPINAL-CORD DISEASES: TABES.—Tabes is the term which is gradually being universally adopted to describe the disease popularly known as "locomotor ataxia." The name "ataxie locomotrice" was given to this affection by Duchenne in 1858 and is still quite popular. It is objectionable, however, because it is merely descriptive of a symptom, which at times may not appear until late in the course of the disease, or which may be entirely absent. "Posterior spinal sclerosis" is also unsatisfactory, as it refers only to the most easily discoverable lesion. "Tabes dorsalis," or "wasting of the back," was applied by Hippocrates to certain symptoms supposed to be due to venereal excesses, but was restricted to this disease by Romberg.

Tabes is the most common form of chronic organic disease of the nervous system. The pathological process underlying the affection is a parenchymatous degeneration terminating in sclerosis, which principally involves the sensory neurones. The peripheral motor neurones are also frequently implicated. In other words, it may be looked upon as a degenerative disease affecting various parts of the entire nervous system, while the most pronounced and extensive lesion is found in the posterior columns of the spinal cord. The morbid process may attack the cranial nerves and their nuclei as well as the peripheral nerves in the extremities. It may thus produce blindness from gray degeneration of the optic nerves, or paralysis of ocular muscles from degeneration of the nerve nuclei. The brain cortex does not always escape. The parts first affected in tabes are usually the fibres which originate in the spinal ganglia, *i.e.*, the fibres of the posterior roots which traverse the posterior columns.

Etiology.—In the vast majority of cases there is an antecedent history of syphilitic infection, antedating the first signs of the disease by from one to thirty-five years. In most cases the period ranges from five to fifteen years, the previous existence of syphilis being either demonstrable or admitted by the patient.

Statistics collected from various reliable sources show that from seventy to ninety-five per cent. of all tabetics give a history of previous syphilis. Hence it has been assumed by nearly all clinical investigators that tabes is one of the results of syphilis. Strümpell has expressed the view, which has been favorably received, that tabes does not arise from the syphilitic bacteria themselves, but from a toxin derived from them. It has therefore been almost universally considered as a sequel of syphilis, and has been variously characterized as a "post-," "para-," or "metasyphilitic" process. On the other hand, it is well known that only a small percentage of those who have contracted syphilis develop tabes. It cannot be consistently denied, however, that tabes also occurs without any discoverable evidence of previous syphilis. With the previous knowledge of an antecedent syphilis in a given case, we are by no means certain that the tabetic degeneration is the result of such early infection. It would seem that in most cases additional exciting or accessory causes are operative, such as exposure to cold, over-fatigue, alcoholic, sexual or other excesses, or a congenital or acquired neuropathic constitution—causes which predispose to the development of tabes, as well as to other degenerative processes, in the nervous system, in those patients who have contracted syphilis at some remote period.

Tabes has at times been considered as resulting from trauma, but in all such cases that have been investigated it has been shown that tabetic symptoms existed before the injury. It is a well-established fact, however, that the tabetic process is accelerated under such circumstances.

Symptoms.—Among the early symptoms of the disease first noticed by the patient are pains in the trunk and extremities; disturbance of the bladder; impotence; rectal pain; diplopia; ocular paralysis; failing vision; cutaneous hyperæsthesia or anæsthesia; incoördination in walking; visceral symptoms known as "crises" affecting the gastro-intestinal tract, bladder, or rectum, and occasionally laryngeal "crises."

Pain is often one of the earliest symptoms of tabes, and may antedate all other symptoms for many years. The character of the tabetic pains is as a rule pathognomonic. They are irregular in their distribution and are usually described by the patient as "shock-like," "sharp," "piercing," "cutting," or "stabbing," being rapidly repeated at the same spot, which often becomes extremely sensitive to the slightest touch. They may also resemble the painful sensation as if the muscles and bones were being crushed, or as if a piece of nerve was pulled. They may be so sudden in their onset that a strong man is surprised into a loud exclamation of pain while feeling otherwise well. They may occur every few moments for minutes, hours, or days. Although they differ essentially from true neuralgic, muscular, or periosteal pains, they are often erroneously considered as being of such origin. Hence it is a common experience for the neurologist to receive such patients with their announcement that they had previously been under treatment for rheumatism or neuralgia. In order fully to appreciate the significance of these pains, it is necessary to study this symptom carefully and minutely, for it may exist for several years before other symptoms are at all prominent. In the majority of instances, the pains most frequently affect the lower extremities. They may, however, be limited to the inframammary, intercostal, dorsal, or lumbar regions. Indeed, they are known to attack almost any part of the body. They may thus appear in the form of trigeminal facial pain or be located in the scalp. On the other hand, in some patients, pain is either entirely absent or only a slight, dull, circumscribed, and aching pain is occasionally complained of. If such pains do not appear in the early period of the disease, they are not likely to appear later.

Crises.—At almost any stage of the disease suddenly recurring paroxysmal attacks of severe gastralgia may take place, accompanied by exhaustive vomiting, which resists all ordinary methods of treatment, but seems to subside spontaneously. These attacks are known as "gastric crises." Sometimes persistent gastralgia may be the only symptom complained of. In such a case careful examination will often reveal an area of cutaneous anæsthesia in the epigastric region, thus leading to further investigation which discloses the underlying cause of the pain. Instead of these "gastric crises," there may be severe and unaccountable diarrhœa associated with violent colicky pain that may sometimes simulate an attack of renal colic. In some instances the rectum may be the seat of severe pain that is remittent in character. This pain not being relieved by ordinary means, its true nature being overlooked, surgeons have been led to the fruitless operation of forcibly stretching and paralyzing the anal sphincter and removing any hemorrhoids that perchance are present.

"Laryngeal crises" occur only in a very small percentage of cases. The most common form is true laryngeal spasm, with noisy inspiration and expiration, cough, and often considerable dyspnœa. The paroxysms may resemble those of whooping-cough or of laryngismus stridulus. Death during these attacks is extremely rare.

Incontinence or retention of urine is frequently an early symptom. Considerable effort is required in micturition, the urine flowing slowly. Quite often the bladder is not completely emptied and the residual urine may undergo decomposition and thus set up a cystitis.

Impotence may also occur as an early manifestation, but it usually develops as the disease advances.

Diplopia, ocular paralysis, or *failing vision* may be the first symptom that leads the patient to consult a physician. For several years before other symptoms are clearly manifested, or at any time in the early period of the disease, there may be frequent diplopia, or transient attacks of paralysis affecting the ocular muscles; these attacks are of nuclear or peripheral origin. The paralyses of the external ocular muscles are often bilateral, but not symmetrical, often unilateral, and frequently affect only single muscles. Ptosis and paralysis of one or more muscles supplied by the oculomotor nerve, and abducens paralysis, are the most frequent. As a rule they develop suddenly and usually disappear after a longer or shorter period, with or without treatment. Relapses are frequent. Attention may first be drawn to the disease through a sudden third- or sixth-nerve paralysis, either partial or complete. The duration varies from a few hours to a year or more, or the paralysis may become permanent. Sometimes both eyes are affected, and a progressive and complete ophthalmoplegia may ultimately develop.

Atrophy of the optic nerve is the most serious ocular complication of tabes. It occurs in about ten or fifteen per cent. of the cases. For a long time it may be the only symptom of the disease, thus appearing several years before other characteristic phenomena are manifested. It rarely develops in the later period of the disease. The atrophic process is the result of gray degeneration of the optic nerves similar to that which attacks the posterior column of the spinal cord. The failure of sight usually commences with a peripheral limitation of the field and loss of color vision (the visual field for green contracting early); but sometimes central vision is defective from the very beginning. The atrophy is almost always bilateral, being more advanced in one eye than in the other, and ultimately progresses to complete blindness. It is rare for tabetic patients who become blind at an early stage of the disease to become ataxic later; but if the ataxia has become well pronounced, it does not always improve with the subsequent development of optic atrophy. In the majority of instances, the occurrence of optic atrophy seems to inhibit the further progress of the disease. This is a peculiar clinical fact which has never been satisfactorily explained.

Incoördination, or ataxia as it is familiarly termed, is a common symptom in many cases of tabes and most frequently affects the lower extremities. It has occasionally been noted by the patient himself, who first discovers difficulty in standing or walking with closed eyes.

As a rule, the lower extremities are affected first. When the sclerosis begins in the cervical portion of the cord, the ataxia, as well as other symptoms, may, for a longer or shorter period, be confined to the upper extremities. It is a curious clinical fact, previously mentioned, that, in cases in which optic atrophy appears, the ataxia often ceases its further progress.

Incoördination is a disturbance of the associated muscular action which is essential in the maintenance of equilibrium. Coördinate muscular action is kept under the patient's control to a certain extent by the attention and vision. As soon as the patient fails to watch his movements, or the eyes are closed, the ataxia is materially increased and may become uncontrollable. Thus, while standing with closed eyes and the feet close together, he may gradually or suddenly fall to the ground (static ataxia), being deprived of the sense of position of the legs, unless the eyes are opened. Incoördination affecting the lower extremities is productive of the characteristic tabetic gait ("locomotor ataxia"). In attempts at walking, when the condition is well pronounced, the foot is lifted from the ground at a much higher elevation than normal, and, being poised with considerable uncertainty, it is suddenly brought to the ground, striking forcibly on the heel.

The ataxia is due to an obstruction or obliteration of afferent impulses conducted from the periphery through the various sensory tracts. It therefore follows as a result of sclerosis of the posterior columns of the cord, or of degeneration of the peripheral sensory fibres in the muscles and joints, being directly conditioned by a loss of muscle and joint sensibility.

While in some cases it is often the most striking symptom, occasionally developing during the first years of the disease in conjunction with other discoverable signs, in many instances the ataxia is scarcely perceptible or demonstrable, or does not appear at all at any time during the course of the malady. Hence the designation of the affection as "locomotor ataxia" is a misnomer.

Sensory Disturbances.—Various paræsthesiæ are often complained of, such as numbness or formication in the extremities—a sensation as if the soles of the feet were resting upon rubber or fur; a band-like feeling around the body, usually at the level of the midthoracic region, as if a tight corset or belt enveloped the body. This sensation is known as "cincture feeling" or "girdle sensation." Or the patient discovers that sensibility in his legs is absent in various areas. In the upper extremities there may be numbness in the course of the ulnar nerve affecting especially the fourth and fifth fingers. In addition to the pains and paræsthesiæ described by the patient, disturbances of cutaneous sensibility are often found upon examination, in association with the loss of muscle and joint sensibility just mentioned. Impairment of sensation may be entirely absent, but in most cases of tabes some objective sensory disturbance is always found. It may vary from slight diminution of tactile sensibility to the most pronounced analgesia. The different qualities of sensation should always be tested carefully. In a large percentage of tabetics (four-fifths) there is an area of diminished sensibility to touch situated like a band about the chest in the midthoracic region and varying from three to four inches in width. This tactile loss may be associated with analgesia in the same area. A diminution in the sense of touch, pressure sense, and the sense of position of the limbs, usually appears in the early stage, while the higher degrees of anæsthesia are developed later. The temperature sense may remain unimpaired until the last stage of the disease. But analgesia is one of the earliest and commonest forms of sensory disturbance. The areas of analgesia may be distributed over the trunk and extremities. In the lower extremities it involves the sole of the foot, the heel, the toes, the anterior or lateral portions of the legs, or the inner surface of the thigh. The transmission of painful sensations is retarded in some cases, the prick of a needle being interpreted at once as a touch, and recognized as a painful sensation from three to ten or fifteen seconds later. This is generally described as "delayed conduction."

The loss of joint sensibility and of the sensibility of the deeper muscular structure occasions interference with the normal muscular "tonus" and results in deficiency or complete relaxation of muscular tension (hypotonus). This condition will explain the fact why tabetic patients submit to extreme passive movements of the extremities without complaint of pain. It may also account for the occurrence of hyperextension of the knee-joints often seen in tabetics (genu recurvatum).

Although patients often complain of weakness in the legs, it is only in exceptional instances (in which the motor neurone system becomes implicated) that such condition can be actually demonstrated. As a rule, the muscular power and resistance to passive movement are unimpaired. When muscular atrophy or actual paralysis exists, they must be considered as complications arising in the course of the disease.

The Loss of the Knee-jerk.—One of the earliest and most constant objective signs of tabes is the loss of the knee-jerk. As a rule it does not disappear suddenly. The pains may exist for a long time before the knee-jerk disappears. In the study of a large series of cases the knee-jerk symptom is found to be variable in its character. In quite a number of instances of undoubted tabes both knee-jerks may be active, but they usually disappear as the disease advances. This occurs when the upper portion of the cord is first affected. In other cases, the knee-jerks may be well marked on one side and lost on the other. Again, they may be apparently absent, but demonstrable only upon so-called reinforcement. Both may be equally feeble, or may differ in degree of weakness

It has been claimed that in about one per cent. of healthy people the knee-jerk is absent. The correctness of this assertion is questionable. Such an anomaly is so rare that its possibility need only be remembered. The writer has tested over one thousand healthy children from three to fourteen years of age, and the knee-jerk was demonstrable in every case. Its absence is due to an interruption in the so-called reflex arc in relation with the corresponding centre situated in the lumbar region of the cord. Much patience is often required in satisfactorily determining whether the knee-jerk is present or absent. The ordinary and customary method of testing for the knee-jerk while the person's legs are crossed, or the feet resting on the floor, will suffice when the knee-jerks are quite active. Under such circumstances the position of the limbs is immaterial. The utmost care, however, is necessary when there is any doubt as to the presence of the reaction. It will then be advisable to have the patient sit upon a high chair or upon the edge of a table, so that the feet are free from the floor. As a rule, both sides should be examined. In many instances the anticipation of the tap upon the tendon occasions involuntary rigidity of the flexor group of muscles, thus producing sufficient opposition to overcome the action of the quadriceps. Hence, before and during the examination, the patient should close his eyes, and his attention should be directed from the purpose of the examiner, either by conversation or by rapid interrogation. Or he may be directed to make some muscular effort with his hands, such as forcibly interlocking the fingers, elevating the arms, etc. This is known as "re-enforcement." With this object in view any other similar expedient may be resorted to that suggests itself to the examiner. It is never safe to state that the knee-jerk is absent, unless repeated and varied tests have been made with the clothing removed.

Reflex Iridoplegia.—Another early and most important evidence of tabes is the loss of the reflex action of the iris to light. This is familiarly known as the "Argyll-Robertson symptom," but in recent years it is more correctly described as reflex iridoplegia. It is present in about eighty per cent. of all cases. Being a phenomenon somewhat analogous to that of the loss of the knee-jerk, it is found to be just as variable in the extent of its manifestations. Its absence, however, does not exclude the diagnosis of tabes. The longer the duration of the disease, the more likely are we to find this sign. When present it is generally bilateral. In rare instances it is unilateral—*i.e.*, affecting only one eye, or the degree of reaction may differ in the two eyes. It is usually unaccompanied by any disturbance of vision. As a rule, the pupils react in convergence of the optic axes. In some cases of tabes the pupils are absolutely rigid, and do not react to light or in convergence. They may also be unequal, partly dilated or contracted. The inaction of the pupil when exposed to light is not indicative of a lesion in the spinal cord, as was erroneously supposed by many before tabes rested upon a firm pathological basis, but is the result of interference with the reflex conducting path in its course between the optic nerve, corpora quadrigemina, and oculomotorius. It is therefore due to a lesion within the brain, and may be looked upon as an almost infallible sign of central nerve degeneration involving the sphincter nuclei of the third nerve or their efferent fibres when the eyes are otherwise apparently normal.

The examination of the pupils for reaction to light requires the closest observance in its performance. This apparently simple procedure is deserving of careful attention, and certain precautions are absolutely essential in order to avoid erroneous conclusions. The following method should be pursued: Place the patient in a position facing a window. Daylight is always preferable. Instruct him to gaze steadily upon some large object at least twenty feet distant, and to keep both eyes open. The eyes are then covered or shaded either with the examiner's hands or with two pieces of dark card-board. The patient in the mean time must continue gazing in the direction just mentioned. In a few moments one eye is suddenly uncovered and exposed to the light, when in the normal state the pupil (which always dilates in darkness or subdued light) immediately contracts. The other eye is then tested in the same manner. The next step is to note if the pupils contract in convergence or accommodation. After the patient has been looking in the distance for a short time, with both eyes uncovered, he is suddenly told to look at the examiner's finger, or some small object held within two inches of the patient's nose. In the normal condition the eyeballs converge and the pupils contract. The pupillary reactions should not be tested before a gas flame, as the patient is apt to, and in fact generally does, "fix" upon the flame, thereby causing contraction of the pupils in accommodation and convergence, which may easily mislead. A very common source of error to be guarded against, which is similar in its result, is the failure to bear in mind the natural tendency of the patient to look at the examiner as soon as the eye is uncovered. Bilateral reflex iridoplegia may also be associated with myosis. While the former often exists without the latter, myosis is as a rule accompanied by loss of the pupillary light reflex. The myosis, however, is due to a lesion affecting the spinal cord and involving the so-called cilio-spinal centre situated between the fourth cervical and the second dorsal segments. As the pupil-dilating fibres pass from thence out by the rami communicantes into the cervical sympathetic, degeneration of these fibres causes the permanent contraction of the pupils.

Arthropathy.—Trophic disturbance in the bones and joints is an occasional phenomenon of tabes, but it is of sufficiently frequent occurrence (in about three or four per cent. of all cases) to command attention. This form of joint affection is known as "tabetic arthropathy," and most commonly involves the knee-joints, although the hip-joint and the large joints of the upper extremities may also be similarly affected. It has often been known to arise during the early or pre-ataxic stage of the disease. Painless swelling and complete disorganization of the joint are pathognomonic of tabetic arthropathy. It usually arises suddenly and develops rapidly. Sometimes following a trivial injury, the joint becomes swollen and the surrounding tissues œdematous, but there is complete freedom from pain, redness, or fever. The joint structures, including the ends of the bones, undergo rapid destruction.

The long bones at times become brittle and thus easily fracture either spontaneously or from a slight traumatism. Among the trophic cutaneous disorders, perforating ulcer of the foot is the most common. It is usually situated on the plantar surface of the foot, either under the base of the great toe or of the fifth metatarsal bone, or at the heel. It generally begins as a callus or corn, and is painless, even when the ulcerative process is quite deep and extensive.

Diagnosis.—The appearance of a classical case of the well-advanced disease, as described in the text-books, is a familiar picture. There is a superabundance of convincing proof to establish the fact that this, probably the commonest form of organic nervous disorder, often remains unrecognized for months or years during its early stages, although ample evidence of its presence may be discoverable by proper methods of investigation. To the most sanguine neurological mind the approach of the medical millennium does not imply the restoration to life and normal function of sclerosed and destroyed nerve structures; but if our modern therapeutic measures are to prove curative in this disease, they must be utilized before organic changes are too far advanced. Our only hope of success in the treatment of tabes rests in a correct diagnosis at the earliest possible moment. The early diagnosis of tabes—which, so to speak, is chronic from its very beginning—is of incalculable value, inasmuch as it saves the patient much misdirected and useless medication. When unrecognized tabes has existed for some time, various pronounced symptoms may appear, and, although a part of the disease, may conceal its true character. Its presence is frequently unsuspected by the attending physician until the signs are so conspicuous that they almost speak for themselves. Although static ataxia frequently occurs in tabes, it is by no means pathognomonic. The fact that a slight swaying is of common occurrence in healthy individuals should always be borne in mind. Static incoördination is often present in hysteria or pronounced neurasthenia, during convalescence after prolonged illness, in transverse myelitis, and in polyneuritis resulting from diphtheria, alcohol, lead, arsenic, etc. Some forms of alcoholic polyneuritis are commonly mistaken for tabes on account of their resemblance to that affection (see the sections on Neuritis and Polyneuritis in the article on *Neuritis*). Upon superficial examination the presence of static ataxia with anæsthesia and absence of the knee-jerk, points to tabes. But as these symptoms are usually associated with tenderness on pressure over the affected nerve trunks, diminished muscular power or actual paralysis, and decrease or loss of faradic irritability in the affected muscles, we are enabled to exclude tabes. The absence of the knee-jerk in these cases is due to involvement of the motor fibres of the anterior crural nerve or its branches, and is usually an accompaniment of weakness or diminished resistance in the quadriceps. The loss of the knee-jerk in uncomplicated cases of tabes, however, is attended as a rule with preservation of muscular power in the extensor group, even when the disease is well advanced and there is pronounced incoördination. This peculiar feature of tabes can be easily demonstrated, and in my experience is of extreme value. When the peripheral sensory nerves are especially affected, as in certain forms of toxic polyneuritis, particularly from arsenical poisoning, the disease has been termed pseudotabes. On account of the presence of well-marked ataxia, absence of the knee-jerks, and anæsthesia, it closely resembles the true disease. A consideration of the antecedent history, mode of onset, and development will generally enable us to reach a satisfactory conclusion as to the nature of the trouble. At times the differential diagnosis between tabes and some atypical forms of polyneuritis is attended with much difficulty. On the other hand, in some tabetic patients the peripheral nerves of the lower extremities may undergo degeneration, and thus lend confusion to the otherwise stereotyped picture. I have repeatedly seen chronic transverse dorsal myelitis mistaken for tabes, owing to pain in the lower extremities, inability to stand with closed eyes, and cutaneous anæsthesia. Such an error must be ascribed to gross carelessness or neglect in the examination. The exaggerated knee-jerks with probable ankle clonus, and the loss of muscular power sometimes with atrophy, should serve to make the diagnosis clear. Some cases of cerebrospinal syphilis so closely simulate genuine tabes that their differentiation can be accomplished only after a careful study of the development and course of the symptoms. Paretic dementia and tabes are sometimes found associated, but when the mental symptoms predominate, such as changes in the patient's character, diminution of the intellectual functions, speech disturbances, attacks of unconsciousness, etc., we must favor the diagnosis of the former.

The most important subjective symptom is the peculiar paroxysmal pains, while the two principal objective signs of tabes are the absence of the knee-jerk and the loss of the pupillary light reflex. It may be safely said that the coexistence of the latter is equivalent to the diagnosis of tabes. It rarely happens that both are absent at the same time, yet such cases do occasionally occur. We must then depend upon the association of other symptoms and must watch for further developments. The presence of either one, in conjunction with the fulgurating pains, or bladder disturbance, or the areas of anæsthesia over the back, is sufficient evidence to warrant the diagnosis. When a man over thirty years of age, with a history of ancient syphilitic infection, complains of the pains characteristic of tabes, we should at once suspect its existence, whether other signs are present or not. Should these typical pains be associated with one or more of the objective symptoms, the diagnosis may be made with confidence. It is a fact well known to all neurologists, that among physicians in general the failure to recognize the presence of tabes is more common than its diagnosis. On the other hand, an incorrect interpretation of phenomena which resemble those of tabes is of frequent occurrence. Such conditions can be obviated only, first, by a clear conception of the clinical peculiarities of the disease; second, by a practical familiarity with the method of examination, combined with its application to the individual case.

Duration, Course, and Prognosis.—Tabes is not invariably progressive in character, but it is always chronic in its course, the average duration of the disease being about ten years, although in uncomplicated cases it has frequently lasted for from twenty to thirty years. In rare instances it is very rapid in its progress, terminating fatally in a few years. As the clinical types differ materially, the course and duration of the disease vary with the character and severity of the symptoms. Remissions have been known to occur, and under suitable management the disease often becomes stationary in its early stages. Occasionally, even in well-advanced cases, the amount of improvement is often very great. The development of cystitis may at times lead to fatal pyelonephritis, and falls or slight injuries may result in fractured bones or in a rapid advance of the pathological process. The characteristic pains, slight ataxia, and absence of knee-jerk and pupillary light reflex may exist for many years without any further manifestations. In some cases the symptoms are so moderate that the patient may live in comfort and be able to be about for many years, while in others the intensity of the symptoms may be so pronounced that the patient becomes bedridden in a year or two.

Treatment.—Although the tabetic degeneration cannot be cured, much can be accomplished by improving the general health of the patient, and thus, in many instances, delaying the further progress of the disease. Hence such measures as prolonged rest in bed, if necessary, judiciously applied hydrotherapy, massage, and static electricity often prove valuable. It is essential to avoid fatiguing exercise or excesses of any kind. Certain subjective symptoms may also be relieved. Objective symptoms, such as optic atrophy, reflex iridoplegia, and absent knee-jerks, always remain permanent despite any form of treatment. The effect of drugs on the tabetic process is very misleading on account of the spontaneous remissions that are known to occur in the course of the disease. Besides, the result of the administration of medicinal remedies in a given case cannot be predicted upon the basis of its beneficial influence in another patient. As the disease varies in its type in different individuals, the plan of treatment will have to be modified accordingly. The patient should be cautioned to avoid any unnecessary exposure to falls or other injuries, for the osseous structures are often brittle and fractures are easily produced. The condition of the bladder must be carefully watched and the urine frequently examined. At the first indication of decomposition of residual urine, or of any symptoms of cystitis, the bladder should be irrigated and the patient instructed in the aseptic use of the catheter.

Tabetic patients who have had syphilis, but who have never received antiluetic treatment since tabetic symptoms have developed, should be given a thorough course of active medication for several weeks. If this has already been carried out without relief, it is useless—nay, even harmful—to repeat the procedure. Not only have I never seen such patients improved by this means, but I have repeatedly noted an increase in the degree of many of the symptoms, presumably as the result of interference with the general nutrition. One difficulty in this matter lies in the possibility of mistaking cases of exudative cerebrospinal syphilis for tabes, *i.e.*, an inflammatory for a degenerative condition. When such a differentiation is not clear or is apparently impossible, the patient should be given the benefit of any reasonable doubt, and antisyphilitic drugs administered.

Pain.—If the action of the bowels is regulated and the diet and general habits of the patient are properly controlled, the frequency and severity of the tabetic pains will be invariably ameliorated, or the attacks may subside entirely. The faradic wire brush, or linear cauterization applied over the vertebral column in the region corresponding with the posterior roots that are presumably associated with the location of the pain, often proves effective. Various anodyne liniments, or the application of an ice-bag or of hot water to the seat of the pain during the attack, give relief in some cases. When necessary, the various coal-tar products may be tried. The most useful are acetanilid and phenacetin. As a last resort codeine or morphine may be administered. During a "gastric crisis" the best method of relief is the subcutaneous injection of morphine or codeine.

Suspension.—This is often useful in selected cases, but it should never be used indiscriminately. The patient may be suspended in a Sayre apparatus for about two or three minutes twice a week. The same result (*i.e.*, stretching of the vertebral column) may be accomplished by having the patient sit on the floor, and then forcibly flex the head and trunk upon the thighs, while the lower extremities are kept straight.

Educational Exercises for Controlling the Ataxia.—This plan of treatment was introduced to the medical profession in the year 1889 by Dr. H. S. Frenkel, of Heiden, Switzerland. A large variety of exercises may be practised. They may be executed with the patient in a recumbent position; while sitting; in an erect position; and various movements may be carried out while walking.

Exercises for the Trunk and the Lower Extremities.—While recumbent: (*a*) Lying on the back, raise body into sitting position and return to recumbency. (*b*) Flex thigh upon abdomen, leg upon thigh, then extend and elevate entire extremity and slowly return to original position. (*c*) Elevate entire extremity while in extension and return (Goldscheider).

The following movements have been recommended by Dana as a modification of Frenkel's method:

"1. Sit in a chair, rise slowly to erect position, without help from cane or arms of chair. Sit down slowly in the same way. Repeat once.

"2. Stand with cane, feet together; advance left foot and return it; same with right. Repeat three times.

"3. Walk ten steps with cane, slowly. Walk backward five steps with cane, slowly.

"4. Stand without cane, feet a little spread, hands on hips. In this position flex the knees, and stoop slowly down as far as possible; rise slowly; repeat twice.

"5. Stand erect, carry left foot behind and bring it back to its place; the same with the right. Repeat three times.

"6. Walk twenty steps, as in exercise No. 3; then walk backward five steps.

"7. Repeat exercise No. 2, without cane.

"8. Stand without cane, heels together, hands on hips. Stand in this way until you can count twenty. Increase the duration each day by five, until you can stand in this way while one hundred is being counted.

"9. Stand without cane, feet spread apart; raise the arms up from the sides until they meet above the head. Repeat this three times. With the arms raised above the head, carry them forward and downward, bending with the body until the tips of the fingers come as near the floor as they can be safely carried.

"10. Stand without cane, feet spread apart, hands on hips; flex the trunk forward, then to the left, then backward, then to the right, making a circle with the head. Repeat this three times.

"11. Do exercise No. 9 with heels together.

"12. Do exercise No. 10 with heels together.

"13. Walk along a fixed line, such as a seam on the carpet, with cane, placing the feet carefully on the line each time. Walk a distance of at least fifteen feet. Repeat this twice.

"14. Do the same without cane.

"15. Stand erect with cane; describe a circle on the floor with the toe of right foot. Same with toe of left. Repeat twice.

"Between the fifth and sixth exercises the patient should rest for a few moments."

All exercises must be performed slowly and deliberately and repeated several times according to the amount of fatigue produced. Some of the principal movements have just been described. Many modifications or additions may be followed, according to the condition of the patient. For more elaborate details relating to all forms of exercises for the upper and lower extremities, the reader is referred to Frenkel's book on "The Exercise Treatment of Tabetic Ataxia."

As all tabetic patients are not ataxic, and as all ataxic tabetics are not suitable subjects for such exercises, this method of re-educating the cerebral centres for coördination will be found to have well-defined limitations. Great care and watchfulness are necessary in carrying out this plan of systematic exercise, particularly in advanced cases. Unless practised persistently and systematically, preferably under the immediate supervision of a competent attendant, the results are usually unsatisfactory. Under suitable conditions, patients who were formerly unable to stand without assistance have been enabled to walk. *William M. Leszynsky.*

SPINAL-CORD DISEASES: TUMORS.—Practically all of our knowledge of spinal-cord tumors that is of any import for clinical medicine has come in these last two decades. It is true that, over thirty years ago, von Leyden put medical literature under a great debt by his published studies of one very interesting case, and within a few years after that he succeeded in showing that the diagnosis of the location and of the nature of a spinal-cord tumor is not impossible to the careful clinician. Before this only the pathological anatomists had given any attention to tumors lying within the spinal canal. Of these, two men deserve mention, because of the thorough manner in which they studied the subject and suggested at least the possibility of progress in clinical medicine up to a point where even this obscure condition might be recognized with certainty, its progress foreseen, and possibilities of surgical interference discussed. These two men are Virchow, in Germany, and Cruveilhier, in France.

The most important practical progress in our knowledge of spinal-cord tumors was to come from England. In 1886 Gowers, having demonstrated many times that it was possible to determine exactly the location of tumors of the spinal cord, recommended that when the diagnosis was satisfactory and conclusive, operative interference should be undertaken. Some years before this Erb, at Heidelberg, had made the same suggestion, though it did not for the moment attract much attention.

Gowers' recommendation was destined to bear fruit very shortly. In 1887 Gowers and Victor Horsley, after thorough discussion of a case of spinal-cord tumor, proceeded to operation, and Horsley removed the tumor successfully, the patient recovering completely and without any serious sequelæ. This classical case deserves to be recalled as the first step in a new and brilliant chapter of surgical therapeutics. It is described in a paper by Horsley and Gowers in the *Medico-Chirurgical Transactions*, London, 1888.

The patient had suffered from pain referred to the middorsal region for four years, which was suspected at first to be due to an aneurism. Certain neurotic symptoms superadded to the pain made some observers consider the symptoms functional. The pain continued off and on for four years; then the left leg became weak and later the right, with complete loss of power. Sensation was impaired and retention of urine occurred. Absolute palsy of the legs was present just before the operation was decided on, with loss of sensation in the trunk as high as the ensiform cartilage, and severe girdle pains were felt in the sixth and seventh intercostal spaces, more on the left than on the right. From time to time the legs became rigid in extensor spasm and the reflexes were much exaggerated. There was no tenderness and no deformity of the spinal columns. Potassium iodide had been used in vain.

At the operation the arches of the fourth, fifth, and sixth dorsal vertebræ were removed, but no tumor was found. The third and seventh arches were removed without any more success. As the patient's condition was good, his second dorsal arch was also removed, when the lower end of the tumor appeared. A portion of the first dorsal arch was cut away to facilitate its removal. It proved to be a fibromyxoma that could be easily lifted from its bed in the lateral column of the cord. The patient made a good recovery and gradually sensation and motion returned. A year later he was doing sixteen hours of work a day, standing and walking most of the time. Horsley and Gowers suggested that spinal tumors were more operable than tumors of the brain, and reported a certain number of cases collected from the literature in which operations would probably have been successful.

This demonstrated that spinal tumors were not as hopeless as had been thought. In the *American Journal of the Medical Sciences* for 1895, page 614, Dr. M. Allen Starr collected the reports of 122 cases of tumor of the spinal cord, with regard to 100 of which fairly satisfactory histories were obtainable. In all of these the diagnosis might have been made before death, and of the 100 cases there were 75, in Dr. Starr's opinion, in which the tumor could have been removed. He also reported, apart from the 127, 22 cases in which operations had been performed. In 2 of these the tumor was not found. In 1 it was impossible to remove it when found. In 11 cases death took place soon after the operation. Eleven patients operated upon recovered, and in 6 the paraplegia completely disappeared; in the other 5 there was relief of symptoms, especially of pain, and some improvement in the gait. Dr. Starr considers then that in nearly seventy-five per cent. of the cases spinal tumors can be operated upon successfully.

In the Versammlung Südwest. Deutsch. Neurologen, held at Baden, 1902, Professor Schultze gave a synopsis of 8 cases of spinal tumors in which operations had been performed. In 2 cases there were errors of diagnosis; of the remaining 6 there were 3 recoveries—2 complete, 1 partial. There were 2 deaths, shortly after operation, and 1 patient remained unimproved. This would give somewhat less than fifty per cent. of prospect of relief from operation.

Dr. Collins, in the *Medical Record* for December 6th, 1902, reports 70 cases of spinal tumor from the recent literature, 30 of which were operated upon. He concludes that spinal-cord tumors are twice as operable as brain tumors, and the results of operation are twice as successful. Fifty per cent. of intraspinal tumors are operable and one-third to one-half of these cases are benefited by operation. Of the 30 operations, 12 were completely successful, 8 were partially successful, and 10 failed to give relief, or the patient died shortly after operation. Of the 70 cases reported, 41 were almost surely operable with hope of relief; 26 were wholly beyond hope. While, then, the outlook for operation in cases of spinal tumors is quite hopeful, Dr. Collins considers that it is not as good as has been represented by previous authorities.

These reports serve to show the present status and the evolution of the surgical treatment of spinal tumors. They serve also to bring out very clearly the fact that neoplasms affecting the spinal cord are by no means hopeless. This has led to thorough discussion of the diagnostic points of spinal tumors, so as to make assurance of their presence and localization as absolute as possible for the guidance of the surgeon. Nowithstanding the progress in this matter, every year some cases are reported in which the tumor fails to be found at operation. In the very first case operated upon (Horsley's cited above) the opening in the spinal canal was made somewhat too low at first. Dr. Collins points out that recent experiences of Starr, Oppenheim, and Schlesinger show that there is danger of localizing the spinal tumor one segment too low, even at the present time. With this precaution it must be admitted that the diagnosis of spinal tumors is as certain as any other bit of internal diagnosis, and definite localization can usually be reached without serious doubt remaining.

Division of Tumors.—Tumors of the spinal cord—that is, new growths affecting the spinal portion of the central nervous system—may spring either from the nervous substance of the cord itself or from some of its coverings. These include not only the spinal membranes (that is, the meninges), but also the periosteum of the spinal canal and the bony column that acts as the support and protection for the cord. It seems better, with the authorities on this subject, to include the bony tumors of the vertebræ. All these tumors give a certain similarity of symptoms, so that we shall consider first tumors of the vertebræ, then tumors which have their origin from the periosteum or from the extradural fat-tissue, then intradural tumors which spring from the inner surface of the dura, from the arachnoid membrane, from the ligamentum denticulatum, from the nerve roots, or from the pia mater, and finally true medullary tumors, which spring from the nervous substance of the cord itself. We may say at once that by far the most important group of tumors is the intradural.

Tumors of the vertebræ have been arranged by Bruns, according to their importance, in the following order: Carcinoma, sarcoma, and osteosarcoma, as also sarcomatoid tumors with myxomatous degeneration, or fibrosarcomata, exostoses, or osteomata, especially multiple exostoses, echinoccus cysts, and finally gummata. There is a pseudo-tumor of the vertebra, due to exaggerated callous formation after fracture of a vertebra, which acts exactly like a tumor, and should accordingly be treated among them.

By far the most important and the most frequent form of tumor of the vertebræ is *carcinoma*. In the great majority of the cases the tumor is not primary, but secondary to cancer in some other part of the body. Vertebral cancer follows particularly cancer of the breast; much more rarely does it occur after stomach or uterine cancer. It is likely, then, to affect especially women, and as a matter of fact the cases of cancer of the vertebræ reported in men are extremely rare. Vertebral cancer may occur many years after an apparently successful operation for cancer of the breast. Bruns reported a case in which eight years had intervened. The late Dr. William Pepper showed to his clinic a case in which over six years had elapsed since the removal of the breast. Primary cancer of the vertebræ occurs very rarely.

As might be expected from the original seat of the tumor, secondary cancers of the vertebræ occur especially in the middle and upper dorsal region, occasionally in the lower cervical region. Primary carcinoma of the vertebræ by contrast occurs more particularly in the lumbar region. Secondary cancer does not limit itself to one vertebra, but apparently from the beginning attacks several. There are in the literature a number of cases in which practically every vertebra from the cervical region down to the sacral region had become carcinomatous. The process may spread by continuity, but it would seem that frequently each vertebral body becomes the seat of a new metastatic focus of malignant disease.

Notwithstanding the wide distribution of the carcinomatous process, the area in which there is pain on pressure or in which there are neuralgic pains due to the irritation of the growing tumor may be very small. Even when there is extensive involvement of the vertebral column, deformity may be absent. The usual deformity is a sinking together of the whole spinal column, a change which the French call *entassement*. In a number of cases patients have been distinctly decreased in height by this sinking together of the vertebræ. Often the bodies of the vertebræ become almost as thin as paper, and it is hard to understand how the patient can hold himself erect. Occasionally there are sudden dislocations of the vertebræ, and these may occur after even very slight trauma. When displacement of the vertebræ occurs, however, there is no true angular deformity as in Pott's disease, but rather a rounded deformity develops. Occasionally thickening and other deformities of the spinous processes can be detected and are pathognomonic. The process extends into the nerve substance very slowly and never goes very far. The spinal nerves may become affected as a consequence of the involvement of the intervertebral openings. The nervous affection may be due only to compression, or it may be a true carcinomatous development. If there is a sudden movement of the vertebræ on one another, the spinal cord may become compressed by the resultant deformity. Slow compression is also possible, because of gradually produced deformity of the vertebral column. The carcinoma may affect the extradural fatty tissue and so compress the cord. In these cases a complete carcinomatous cylinder may surround the dural sac. The tumor is, however, soft in consistence, and so the compression symptoms are unimportant and the real cause of the nervous disturbances is often collateral œdema due to interference with the return blood supply of the cord. In cancer of the vertebræ it is very seldom that the nervous substance of the cord itself becomes malignantly diseased.

Primary sarcomata of the vertebræ are not so rare as primary carcinomata. Sarcomata, however, usually occur in the lumbar or the sacral region and the affection develops by continuity from a tumor in the neighborhood. The viscera in the pelvis particularly are likely to be the seat of the primary tumor. Sarcomata are more malignant than carcinomata. They readily involve the dura, and may even penetrate this membrane and infiltrate the cord itself. A long portion of the spinal column may be affected by a sarcoma before serious symptoms begin. Much more frequently than carcinomata of the spinal column, sarcomata involve the transverse processes, the spines, and the vertebral arches, and may, by pressure of the tumor thus formed, cause perforation of the skin. Sarcomata may occur in very early years, though they are more frequent in advanced age.

Exostoses and osteomata may grow from the transverse processes, or from the spinal arches, or from the bodies of the vertebræ. When they grow from the posterior part of the body of the vertebra, or forward from the arch, they cause compression of the cord and of the nerve roots. They seem to be somewhat more frequent in the lumbar and sacral regions. Usually when an exostosis is present in the spinal column, other portions of the skeleton present similar outgrowths. They should be looked for on the ribs, in the supra-orbital region, along the spine of the scapula, and on the clavicles. Their discovery usually makes the diagnosis of the variety of tumor in the spinal cord plain without more ado.

Echinococcus cysts are rather rare in the spinal column, but they have been noted in a number of reported cases. Sometimes they cause a sudden dislocation of the bodies of the vertebræ and may lead to acute compression symptoms.

Gummata of the spinal column occur most frequently in the upper part of the cervical region. Not infrequently, as has been pointed out by Gowers, they are associated with ulcers of the pharynx. It is always very difficult to differentiate this condition from tuberculous caries of the vertebræ. The differentiation is, however, extremely important, because of the success of therapeutic measures in the syphilitic process. In suspected cases the therapeutic test constitutes the best differential diagnostic sign that we have. When a suspicious symptom develops, especially in relation to the upper cervical region, the patient should be carefully questioned as to his history, as to syphilis, and in any case mixed treatment should be used.

If a vertebral tumor is diagnosed, then its nature can sometimes be determined. The most important element is to know the nature of the primary tumor. Sometimes this will be found to be a lympho sarcoma, and in this case there is some hope that the use of arsenic for a long time, either internally as Fowler's solution or, better still, as sodium arseniate subcutaneously, may do some good. When a tumor of the spinal cord is primary, it is more likely to be malignant than benign. The occurrence of vascular murmurs in the affected region speaks for sarcoma. Symptoms of osteomalacia make the diagnosis multiple myeloma. Osteomata run a very slow course, though it cannot always be said, as Bruns does, that they cause less pain than tumors which run a more rapid course. The echinococcus cysts may be recognized by puncture of the tumor and the finding of hooklets in the secretion. In a number of reported cases echinococcus cysts have been considered by very good authorities to be cold abscesses. In almost any case of vertebral tumor, one of the iodides, potassium or sodium, according to the preference of the physician in charge, should be employed. In most cases, unless the history is very clear and the condition absolutely sure, a mercurial inunction course should be given. The condition in malignant tumors is so hopeless that the erysipelas toxins, or the mixed toxins suggested by Coley, should be employed, and it will sometimes be found that they furnish relief, or even an absolute cure, in unexpected circumstances.

Character of Tumors.—The tumors that develop within the spinal canal are divided into those of the cord itself and those of the meninges. The most frequent are those of the meninges, the proportion being nearly two to one. Of the meningeal tumors, some are intradural and some extradural.

In contrast to the tumors of the vertebræ, most of the intraspinal tumors are primary. In the extradural space, the most frequent tumor is the lipoma, which develops in the extradural fatty tissues. Next after this in frequency is the sarcoma which often develops from the periosteum of the vertebræ, though it also sometimes grows on the outer surface of the dura. There may be tuberculous tumors that grow within the spinal canal without any connection with the vertebræ. Such tumors may extend in their vertical diameter and cover a large portion of the cord. Echinococcus cysts may develop in the extradural space, and a very rare form of tumor, the enchondroma, has been encountered here. In one or two reported cases teratomata have also been encountered.

When tumors begin in the extradural space they very seldom find their way through the dura. Practically all of the tumors that occur outside of the dura are single. Lately a few cases of multiple extradural tumors have been reported.

Intradural tumors spring from the inner surface of the dura, from the arachnoid membrane, from the pia mater, or from the ligamentum denticulatum. True neuromata having their origin in the nerve substance, or pseudoneuromata springing from the sheath of the nerve, are not unusual in the intradural space. Bruns has reported a case in which the nerve root ran directly through the centre of such a tumor. The pathological anatomy of intradural tumors is more diverse than that of the tumors which occur in the extradural space. Practically any of the connective-tissue tumors may occur. Fibromata and fibrosarcomata, as well as genuine sarcomata and the sub varieties, angiosarcomata and myxosarcomata, have been reported. In a few cases pure angiomata have been found.

In children particularly there are a certain number of tumors that occur in connection with congenital malformations, associated with patent or latent spina bifida. These tumors are apt to occur, especially in the lumbar region, though they may invade the lower dorsal region. The most frequent variety is the lipoma. Neuromata are especially apt to occur in the cauda equina. Not infrequently malignant degeneration takes place even in tumors which are really not malignant at the outset. Neuromata are apt to be multiple in the cauda equina. At times degeneration of tumors affecting the nerve substance causes the presence of what is known as brain sand. Such tumors are spoken of as psammomata.

Solitary tubercles occur not infrequently in the intradural space, though tuberculosis affecting the membranes is apt to be diffuse. Nearly the same thing is true of syphilitic processes. Perfectly circumscribed gummata are not very frequent, but diffuse gummatous meningitis is not so rare. Echinococcus cysts are very rarely encountered in the intradural space. Some of them have been found free in the arachnoidal space. Aneurisms of the spinal arteries, theoretically, should be encountered occasionally, but as a matter of fact they are very infrequent.

In general it may be said that the pathological anatomy of tumors which occur within the spinal canal is not different from that of the same form of tumors when they occur in other parts of the body. The consistence of these tumors is rather hard, practically always harder than that of the cord itself: hence the compression symptoms that are produced. Only diffuse sarcomatous and carcinomatous new growths are soft in consistence, and such tumors are apt to be very vascular, making any question of their removal futile. As a rule tumors that grow within the dura are apt to be circumscribed in size, and seldom exceed that of a dove's egg. The limitation in size of spinal tumors is rather favorable for their removal by surgical procedures, and for this reason the prognosis of intradural tumors that are non-malignant is not as serious as it would otherwise be.

Differentiation of Vertebral Tumors.—In differentiating carcinoma of the spinal column from Pott's disease, it may be said in general that Pott's disease is an affection of youth or childhood. It must not be forgotten, however, that tuberculous caries of the vertebræ comes at a later age than any other form of bone tuberculosis. Carcinoma is quite rare, though sarcoma is not infrequent before adult life. It has been said that the intensity of the neuralgia caused by carcinoma is always greater than that due to caries. This must not be accepted as an absolute rule, however, according to the observation of Bruns and Schlesinger. The most important differential diagnostic point between caries and vertebral tumors is the kind of deformity present. Angular deformity is characteristic of Pott's disease. Carcinoma causes a rounded deformity, or else causes, as has been already noted, a shortening of the whole spinal column. If tumor-like masses can be felt alongside the spinal column, or in the pelvis, as is not infrequently the case in sarcoma, the differentiation from Pott's disease is easy. Evidence of the existence of tuberculosis in other organs, or of a cold abscess, makes the decision in favor of Pott's disease. It must not be forgotten, however, that as a consequence of the dyscrasia of cancer, myelitic processes may occur in the spinal cord, and Schlesinger has reported a case in which, notwithstanding the history of carcinoma of the breast, the affection of the spinal cord was a true caries.

Tumors of the upper part of the cervical cord begin usually with pain, and before long areas of anæsthesia develop. The pain is felt along the distribution of the cervical plexus in the area supplied by the supraclavicular nerve, the nervi occipitales minores, at times also the nervi occipitales majores, and practically always in the distribution of the great auricular nerve. Atrophic conditions and palsy of the sterno-cleido-mastoid muscles and the musculi circulares usually develop. The deep anterior cervical muscles, as well as the superficial and deep muscles of the neck posteriorly, are likely to be involved in the same process. After the neuralgia, hemiplegia involving the arm and leg on the side of the tumor gradually develops. In contradistinction from cerebral hemiplegia, there is no involvement of the facial or of the hypoglossal nerves. Anæsthesia occurs on the opposite side as a Brown-Séquard phenomenon. The paraplegic condition, as a consequence of a tumor in the cervical cord, never lasts long, as the involvement of the phrenic nerve soon causes death from respiratory failure.

Tumors of the cervical enlargement of the spinal cord present first a stage of the Brown-Séquard phenomenon. When the tumor is limited to one-half the cord, atrophy and paralysis with anæsthesia and neuralgic pains in the arm on the side of the tumor are soon noted. A spastic paralysis and a disturbance of muscular sensation in the corresponding leg are usual accompaniments; anæsthesia occurs in the leg on the other side and in the opposite side of the trunk, and on the ulnar side of the other arm when the tumor in its growth causes a transverse lesion, a spastic paralysis, and anæsthesia of both legs with palsy of the trunk muscles and anæsthesia of the trunk up to the second rib, are the usual results. In this case there is also paralysis of the arms. If the tumor involves all of the cervical enlargement, there is complete anæsthesia of both arms. If there should be direct involvement of the uppermost dorsal nerve root, myosis and immobility of the pupil occur. If the tumor is strictly limited, these symptoms occur only on one side, though usually they develop on both sides a little later

Tumors of the dorsal spinal cord cause first the Brown-Séquard symptom, and later give spastic paraplegia of the leg and abdominal muscles, and anæsthesia of the trunk up to the level corresponding to the height of the tumor. The neuralgia occasioned is at first one sided, but later it assumes the character of a complete girdle pain. The hyperæsthesia does not follow exactly the intercostal spaces, but is more horizontal in its reflexes. Atrophic paralyses of the intercostal muscles can usually not be demonstrated, though they are noted in the abdominal muscles.

When the tumor begins to compress the cord, and before the compression is so severe as to cause an interruption of the flow of nervous impulses the skin and tendon reflexes are all exaggerated. Patellar clonus and ankle clonus are present. At times even a slight touch upon the lower extremities causes a distinct tremor clonus which was described originally in this country by Brown-Séquard, and designated by him as spinal epilepsy. As the transverse lesion of the cord becomes complete the tendon and skin reflexes decrease. As a rule, however, the skin reflexes remain even after nervous communication through the cord has been completely interrupted. In the so-called Brown-Séquard palsy the paralysis on the side of the tumor is mostly of the spastic variety, and the tendon reflexes are exaggerated. Sometimes when the lesion is very high in the cord an atonic palsy with loss of reflexes is established. Severe trophic disturbances and even a qualitative change of the electric excitability, sufficient to constitute a reaction of degeneration, does not occur as a rule in these cases of paralysis. There are, however, a considerable emaciation and a distinct quantitative reduction of the electrical excitability of the muscle. Sometimes there is, because of a readily produced œdema of the skin, a lowering of the electrical excitability of the paralyzed muscles which simulates the loss of electrical reaction. In these cases, however, while the faradic current may fail to produce any effect, the galvanic current, if strong enough, will always produce quick muscle contraction.

The condition of the bladder and of the rectum, when tumors of the cervical or dorsal cord exist, depends entirely on the extent of the interference with cord functions. At the beginning there is usually only some slight difficulty at the commencement of urination, though the call to urinate is more frequent and more imperative. After a time, voluntary urination becomes impossible and urinary retention sets in. Somewhat later the bladder sphincter loses its power and incontinence results. This takes the intermittent form, so that the bladder empties itself every now and then without the will of the patient, and sometimes the anæsthesia is so marked that he does not notice the flow of urine until he becomes wet. If the whole spinal cord becomes affected, all the bladder reflexes disappear, and its muscles become palsied Nearly always, when paralysis of the bladder occurs, cystitis develops, and this leads to pyelitis and nephritis, and hastens the fatal termination.

The rectum goes through nearly the same functional disturbances as the bladder. At the beginning there is constipation and then later emptying of the rectum becomes impossible by will power. After a time a paralytic condition sets in, though the sphincter maintains enough contractility to retain fæcal material for some time. At intervals of several days, the rectum empties itself spontaneously, especially if there has been the slightest increase of peristalsis or any tendency to diarrhœa.

With regard to the sexual functions, in tumors of the dorsal and cervical region there are certain characteristic symptoms. They occur, of course, only in men. At the beginning of the affection potency remains, and it may even happen that there is an increase of sexual desire. In tumors of the cervical cord priapism may become an annoying symptom. This may not persist constantly, but the slightest manipulation of the penis, as, for instance, for purposes of catheterization, may cause an erection, and this may interfere with the necessary insertion of the catheter in these cases. When there is a complete transverse lesion of the dorsal cord, impotence is inevitable.

Interference with the vaso-motor nervous mechanism and the absence of movement may lead to œdema of the affected leg or legs. In these cases there is dry scaliness of the skin that resembles ichthyosis very closely. The joints may suffer from trophic disturbances, and it must not be forgotten that contractures set in and ankylosis may develop. Bedsores are not frequent in tumors of the cord high up, but when the transverse cord lesion is complete, then skin ulcerations occur as easily as in affections of the lower part of the cord.

Tumors of the lumbar enlargement of the cord cause at first pain in the region of the lumbar plexus. This is usually one-sided, and is referred to the anterior and inner side of the thigh, the knee, and the leg. Next in order comes paralysis of the ilio-psoas muscle, the quadriceps, the adductors, and the tibialis anticus. The Brown-Séquard phenomenon may occur in one-sided affections of the upper part of the lumbar enlargement. When the whole cord is affected, complete paralysis and anæsthesia of the lower extremities develop; at first only in the region of the lumbar plexus, later in the whole leg. Ankle clonus may be present when the knee-jerks are absent; bladder and rectal disturbances and sexual impotence are not so common in lumbar tumors as in those in the sacral region.

Tumors of the sacral cord, if they leave the lumbar enlargement unaffected, cause characteristic symptoms of their own. These are paralysis and wasting of the muscles of the lower leg and of the foot and of the posterior portion of the thigh, especially the gluteal and perineal muscles. At first this may be one-sided, and later, as the tumor develops, it may affect both sides. Anæsthesia is noted first in the foot and then at the back of the leg and thigh, and finally in the perineum and the genitals. Total paralysis of the bladder and rectum occurs, and impotence is a marked feature from the beginning. The Achilles reflex is often absent, though the knee-jerk is present. Bedsores and cystitis occur early in the case.

Tumors of the Cauda Equina.—The lumbo-sacral cord is commonly considered to run from the upper border of the twelfth, or from the lower third of the eleventh dorsal vertebra, to the lower border of the first lumbar vertebra, or at the very most to the middle of it. The lumbar enlargement lies usually beneath the twelfth dorsal vertebra. The sacral portion of it corresponds to the first lumbar vertebra. Below the middle of the second lumbar vertebra, then, there is no longer any cord substance, but only a thick bunch of nerves, the so-called cauda equina. As certain of the nerves that come from the lumbar enlargement of the cord run in the spinal canal, it is easy to understand that the same symptoms may occur as a consequence of a tumor in the lumbar enlargement as when the cauda equina is affected by a similar lesion. There are some differential diagnostic peculiarities, however, which make it possible to draw a distinction at times with complete assurance as regards tumors of these two regions. The first and most important distinction is that tumors of the meninges, when they begin to affect the spinal cord itself, usually cause unilateral symptoms. Tumors in the caudal region, however, usually cause from the very beginning bilateral symptoms. It is possible, however, for a tumor of the cauda equina to cause unilateral symptoms at first. Tumors of the lumbar cord usually cause completely symmetrical paralyses and areas of anæsthesia. This symmetry is apt to be lacking in tumors of the cauda. Caudal tumors are apt to cause very severe pains that persist in spite of treatment and that are very extensive. The pain is apt to be especially severe and obstinate in the sacral and coccygeal region. Tumors of the lumbar cord exceptionally cause very severe pain, so that this distinction is not very important. Friedrich Schultze claims that very marked and extensive fibrillary tremors are a sign that the cord itself is affected, rather than the nerves of the cauda. Bladder and rectal disturbances and trophic lesions of the skin follow both kinds of tumors.

The possibility of more than one tumor developing at the same time within the spinal canal must not be forgotten. In a certain number of reported cases the presence of more than one tumor has been recognized by the definite symptoms produced by each of them, and especially by the successive development of symptoms pointing to more than one localized area of irritation or pressure. Gowers calls attention to the fact that the greatest difficulty exists in the cases in which an intracranial tumor precedes the growth within the vertebral canal, and the symptoms of the spinal tumor are overlooked in the presence of the severe manifestations of the intracranial growth.

There is one form of disease which closely simulates a tumor in the symptoms which it produces. This is hypertrophic pachymeningitis. It always affects the cervical region, and hence the question of its exclusion must always be considered before an absolute diagnosis of the presence of a cervical spinal tumor is made. The differential signs are: that the manifestations of hypertrophic pachymeningitis are usually bilateral, while in the case of a tumor the initial symptoms, at least, are unilateral; and that the manifestations produced by pachymeningitis, instead of being very localized, show an involvement of a considerable portion of the cord in vertical extent.

The symptoms of extradural and intradural tumors of the spinal cord are very similar. There are certain slight differences which with care can be utilized in determining the localization of a tumor. The first symptom in any case is almost sure to be pain. In general, the first mechanical effect of the presence of the tumor is compression of the nerve roots, and then of the spinal cord itself. In this matter, tumors within the spinal canal differ but very little from those which spring from the vertebræ. For a considerable time, at the beginning of the symptomatic course, an irritative condition is noted, which affects especially the sensory nerve roots, causing neuralgias. The reason for this is not far to seek. Intradural tumors occur more frequently in the posterior part of the cord, or posteriorly and laterally. As a consequence, irritation of the motor roots occurs less frequently and seldom leads to recognizable localizing symptoms.

As a rule the pains are intense and typically neuralgic in character, but lack the tender points of true peripheral neuralgia. The pains are described as lancinating or tearing, and are not infrequently accompanied by causalgia—that is, a burning pain in the skin of the region supplied by the irritated nerve. Very often there is an accompanying hyperæsthesia of the skin which makes even the slightest touch unbearable. The pains are always increased when the spinal column is moved, or when there is any shaking of the body, as in coughing or sneezing. The pains may last for days and weeks without any intermission, though there may be intervals of comparative painlessness. The complete destruction of a nerve root causes a stoppage of the pain, and it may take some time for the tumor in its growth to reach another nerve root.

As in the case of vertebral tumors, herpes zoster may occur in the painful hyperæsthetic part. While in vertebral tumors the pains are from the beginning usually bilateral, in intradural tumors they are much more likely to affect only one side. It is easy to understand, however, that tumors of the meninges may affect both sides of the spinal cord, or both nerve roots at a given level, and so cause bilateral neuralgia. At times there are evidences of irritation of the motor roots, though these are seldom present. Painful cramps or tonic contractions of the abdominal muscles, for instance, or of the cervical muscles causing torticollis, have been noted. In these cases the lesion usually affects the sensory roots and the motor symptoms are reflex.

With regard to paralyses and anæsthesia, it must be remembered that the destruction of one nerve root seldom causes the development of such a condition. At least three or more nerve roots must be affected before anæsthesia, or muscle paralysis, will be a prominent feature of the case.

Pain is the most prominent feature of the early history of tumors interfering with the function of the spinal cord. It is prone to occur in attacks that are described as stabbing or tearing in character. It is not unusual, however, for the patient to suffer from dull aches between the severe attacks, or the initial stage of the affection may be characterized by a more or less persistent dull aching discomfort in certain muscles. The result of this is, that not infrequently the diagnosis of chronic rheumatism is made and the patient is treated for that disease. It is not an unusual thing to find that several physicians in attendance upon a given case have spoken of a spinal tumor as muscular rheumatism. As Gowers has pointed out, the pain produced by spinal tumors is intense, and at times so hopelessly obstinate to medical treatment that it has more than once led the unhappy sufferer to attempt suicide. This must be borne in mind by the medical attendant.

The diagnosis of neuralgia is not infrequent in the primary symptomatic stage of a spinal tumor. In contradistinction to true neuralgia, however, there is, as was pointed out by Dr. Starr, an absence of tenderness, as a rule, in the nerves along the lines in which the pain is felt. When the tumor is within the spinal canal, movement does not usually increase the pain; though this is apt to be the case when the tumor is in the bones. Pain is greatest when the tumor is situated so as to compress the cord directly laterally or posteriorly—that is, when it affects directly the sensory nerve trunks.

It must not be forgotten, in diagnosing tumors of the spinal cord, that the irritation of the sensitive nerve substance may give rise in predisposed individuals to symptoms of functional disorder of the spinal cord. Hysterical manifestations are not an unusual accompaniment of the initial stage of tumors of the cord, and often make the diagnosis more difficult than it would otherwise be. The physician's fear is always lest he should exaggerate the significance of neurotic symptoms. As a matter of fact, however, there is more danger of his minimizing the significance of the symptoms of the organic disease present, and so wasting precious time in the initial stage of the affection, when operation may save the spinal cord from lasting injury due to long-continued pressure.

The most characteristic feature for the diagnosis of a spinal tumor, its character and localization, is undoubtedly the course of the symptoms and the careful observation of the history of the case. The symptoms of tumor begin usually with unilateral pain, associated commonly with hyperæsthesia. A little later, one-sided cramps in the muscles are prone to occur, followed before long by paresis and atrophy in the affected muscles. This practically constitutes an index of a lesion involving half the cord. As the growth of the tumor progresses, the other side of the cord also becomes affected and paraplegia develops. A not infrequent accompaniment of this group of symptoms is localized pain, or, in some cases, deformity of the spinal column.

Treatment.—As we have already said, the most favorable form of spinal tumor, as regards therapeutics, is that of syphilitic origin. As Gowers says, syphilis can be excluded only when there has been no possibility of infection. In many cases of late syphilitic lesions there is no history of secondary syphilis, and in others there is no history of a primary sore. Hence it is certain that in some cases of late lesions of syphilis a history of both primary sore and secondary symptoms will be absent, and such cases are actually met with not infrequently in neurological practice. In practically all cases, then, antisyphilitic treatment should be tried for a period of from four to six weeks. The treatment of syphilitic conditions of the spinal cord should be prompt and energetic. The pressure must be lessened as soon as possible, otherwise degenerative changes and at times even hopeless destruction of nervous elements will take place. The influence of a few days' loss of time may make a difference of weeks in the duration of symptoms, and may even make the ultimate condition much less satisfactory.

In cases that are non-syphilitic very little can be accomplished by medication. Sedatives must be employed for the pain, and yet with the greatest care, since habits are so easily formed and anodynes lose their effect. Cocaine may be employed by subarachnoid injection to aid the action of morphine. The state of the bladder must be watched very carefully, it must not be allowed to become overdistended, yet the catheter must be used with every possible aseptic precaution, including especially the cleansing of the fossa navicularis before the introduction of the instrument; otherwise severe cystitis will be likely to develop in the lowered vitality of the vesical mucous membrane. Because of the diminished nutrition of all tissues, bedsores must be carefully guarded against, and if the patient shows early a tendency to their development, a water-bed must be secured without delay.

Spinal tumors that are not within the substance of the spinal cord itself may not infrequently be removed by surgical procedures. As we noted at the beginning of this article, at least fifty per cent. of all tumors are operable, and of these more than one-half may be practically cured or relieved completely of their annoying symptoms. It must be remembered that Gowers and Horsley insist that the early removal of a small growth in the spinal cord may possibly be followed by the regeneration of conducting fibres that are on the other side of the cord, and by the return of their function, lost only through the effects of pressure. As soon, then, as a definite diagnosis of the presence of a spinal-cord tumor is made, operation should be recommended and the state of the case, with the possibility of a complete cure, set before the patient. Delay in this matter can do no possible good, and a delay of even a few months may cause irremediable damage to the delicate nerve structures. In estimating the chances of a successful issue, it must be remembered that the effect of the operation upon the patient's general condition is distinctly unfavorable.

James J. Walsh.

SPINE, DISEASES OF THE.—Syphilis.—Syphilis, in either the inherited or the acquired form, may cause deformity of the spine with accompanying symptoms that can hardly be distinguished from those of Pott's disease. As compared with tuberculosis it is a very uncommon disease of the spine. Its manifestations are likely to be general in character, the local deformity being one of many evidences of disease.

Syphilitic disease of the spine, causing destruction of tissue and deformity, demands the same protective treatment as would progressive deformity from other causes. Appropriate medical treatment is of course indicated in addition.

Malignant Disease.—Malignant disease of the spine is uncommon, particularly so in childhood. Sarcoma is more common than carcinoma, and it may affect the spine primarily, while carcinoma is almost always secondary to disease elsewhere, as of the breast.

The symptoms of malignant disease are usually more severe than those of tuberculosis. The pain, for example, is often persistent and is not relieved by support or recumbency. The constitutional symptoms are more marked and the steady progress of the disease toward a fatal termination is soon apparent. Not infrequently the tumor may be palpated through the abdominal wall, and the deformity characteristic of destruction of the vertebral bodies is often absent. Paralysis is a frequent and often an early symptom.

Malignant disease of the spine is a fatal affection and the treatment can be but palliative.

Acute Osteomyelitis.—Infectious osteomyelitis of the spine is uncommon. The characteristic symptoms are similar to those of acute infectious processes elsewhere, namely, sudden onset with fever and constitutional depression. There are local pain and tenderness about the spine. Abscess quickly forms, and paralysis, from the rapid extension of the disease to the spinal cord, is a frequent complication.

The later symptoms due to pyogenic infection are often pyæmic in character. Necrosis of the affected vertebral bodies may result in the formation of large sequestra. The death rate is about fifty per cent.

Treatment.—The immediate evacuation and drainage of the abscess is indicated together with the removal of the necrosed bone if possible. Subsequently the spine should be supported.

A more chronic and more localized form of osteomyelitis may occur, but it is practically impossible to distinguish its symptoms from those of tuberculous disease. In this class of cases an abdominal or pelvic abscess may be the first indication of disease.

Actinomycosis.—Actinomycosis of the spine is an extremely rare disease. Its diagnosis may be made by the microscopical examination of the discharge from the sinuses that almost always form early in the course of the disease.

Traumatism.—Severe sprains, rupture of ligaments, or fractures of the spine may simulate disease, particularly when the injury is of the cervical region. Diagnosis is in some instances practically impossible until the effect of local support has been tested, when as a rule, if disease be absent, the symptoms, even though of long standing, quickly subside.

Fracture of the spine in the middle region without displacement may cause angular deformity, and when proper support has been neglected, symptoms of pain and weakness similar to those of Pott's disease may persist indefinitely.

Sudden forcible compression of one or more of the vertebral bodies without displacement and without severe immediate symptoms, other than the slight deformity, may be the result of injury, especially falls from a height. These cases are not uncommon and are usually mistaken for Pott's disease, especially as the deformity may not be evident until several weeks after the injury.

The *diagnosis* should be made clear by the history.

Treatment.—In all such cases and whenever weakness of the spine persists and when motion causes pain, a support should be applied. Fracture of the spine should be treated as are fractures elsewhere, by reposition if possible or practicable, and by support until the integrity of the parts has been reëstablished.

Traumatic Spondylitis.—Kümmell has described a form of rarefying osteitis of the spine induced apparently by injury. It is characterized by symptoms of pain and weakness, referred to the back, and by a rounded kyphosis of the dorsal region. Motor disturbances of the lower extremities are frequent. Such cases may be explained either as direct effects of injury, or as due to subsequent infection—tuberculous or otherwise—of the weakened parts.

The *treatment* is similar to that of Pott's disease.

The Rachitic Spine.—The rachitic spine has been mentioned in the consideration of the differential diagnosis of Pott's disease, and it is described in more detail elsewhere. (See *Spine, Tuberculous Disease of the.*) It is a deformity that appears, usually during the first or second year of life, in children who do not walk. The typical rachitic kyphosis is a rounded projection of the middle and lower region of the spine. It is in fact simply an exaggeration of the contour that is normal in the sitting posture. The deformity is more or less rigid according to its duration. If it is extreme, it may be accompanied by a compensatory backward inclination of the head—"posterior torticollis."

Treatment.—Aside from the constitutional treatment of the predisposing disease the indications are to overcome the rigidity and the limitation of motion of the spine, to support it if necessary by a light back brace, and to avoid, as far as possible, the postures that favor the deformity. In severe cases of rickets the recumbent posture on the stretcher frame which has been described under Pott's Disease (see article entitled *Spine, Tuberculous Disease of the*), is the treatment of selection.

The "Typhoid Spine."—During the course of, or during convalescence from, typhoid fever symptoms of pain, weakness, and stiffness of the back may appear, induced in certain instances apparently by sudden movements or strains. Often there may be local sensitiveness to pressure or motion; and a slight posterior projection in the lumbar region of the spine, the part most often involved, is not unusual.

The cause of the symptoms is apparently infection of the fibrous coverings and attachments of the spine similar to the more common and more severe forms of periostitis in other situations that may complicate this disease. It may be stated also that in exceptional instances typhoid infection may be accompanied by abscess, by destruction of bone, and by actual deformity.

Treatment.—The treatment should be symptomatic. During the active stage if the pain is severe the patient should be kept in the recumbent position. Locally the application of the Paquelin cautery is of service in relieving pain, and the application of adhesive plaster strapping over the sensitive area may add to the comfort of the patient. As soon as it is practicable a back brace or corset should be applied. Recovery is the rule, although a certain amount of restriction of motion may persist.

The same symptoms may follow other forms of contagious disease, notably scarlet fever, but as a rule they are less persistent and severe.

Gonorrhœal Arthritis.—Gonorrhœal infection is uncommon. Its symptoms resemble those of the preceding affection; ankylosis is, however, more common as a result; in fact, gonorrhœal arthritis is supposed to be one of the causes of spondylitis deformans.

The treatment consists in support for the purpose of preventing deformity and relieving discomfort.

Cervical Arthritis.—The joints of the occipito-axoid region are sometimes involved in what appears to be a form of infectious arthritis, sometimes following diphtheria or other contagious disease. It may be distinguished from tuberculosis by its acute onset, and from acute torticollis by the fact that all the motions of the head are restricted.

Treatment.—The treatment consists in support during the acute stage, as by a collar or jury mast, followed by massage and manipulation to overcome the stiffness.

Spondylitis Deformans.—Spondylitis deformans is a chronic affection of the spine terminating in ankylosis and deformity.

The disease is apparently a chronic inflammation which affects primarily the ligaments and the periosteal coverings of the spine, a form of ossifying periostitis which binds the vertebræ firmly to one another. It may begin on the lateral or on the antero-lateral aspect of the spine. It may be limited to a particular region, but in most instances it progresses until it involves the entire spine, and often the articulations of the ribs as well. The intervertebral discs atrophy, but in some instances the margins of the cartilages proliferate and become ossified in a manner characteristic of osteoarthritis.

Under the general term of spondylitis deformans are included, in all probability, several varieties of disease. For example:

1. The ankylosis of the spine may be simply a part of a general rheumatoid arthritis involving the larger and smaller joints—rheumatoid arthritis of the spine.

2. The spine may be involved together with one or more of the adjacent joints, which show the characteristic

symptoms of the so-called hypertrophic form of arthritis deformans—osteoarthritis of the spine. This form has been designated by Marie as spondylose rhizomélique (σπόνδυλος spine, ῥίζα root, μέλος extremity), implying a disease of the spine, together with the adjoining "root" joints.

3. The disease may be limited to the spine and even to a particular region; in such cases it may be quite different from rheumatoid arthritis or osteoarthritis. This form may follow acute rheumatism; it may be induced apparently by gonorrhœa or by other forms of infection. It may begin acutely like inflammatory rheumatism, or it may be chronic in character and progress slowly.

FIG. 4422.—Complete Ankylosis of the Entire Spine. The patient, about one year before coming under observation, fell down a flight of stairs, rupturing the bony adhesions between the vertebral bodies at the points of greatest deformity (as seen in the picture). The accident was followed by great pain and marked sensitiveness at and near the points of injury, and these symptoms persisted for many months.

In the cases of spondylitis deformans, as distinct from general involvement of the joints, there is often an acute onset, called lumbago, from which the patient dates the beginning of his trouble. This is followed by a gradually increasing stiffness of the spine and accompanying deformity, with intercurrent attacks of so-called lumbago. In the well-marked cases the patient complains of stiffness, weakness, pain in the loins, pain radiating forward along the ribs; sometimes of weakness in the limbs, of headache, nervousness and the like, symptoms that may be caused directly by the inflammatory process, or by implication of the nerve roots, or by an accompanying neurasthenia. The direct symptoms are increased by jars which are exaggerated by the inelasticity of the spine. The disease is usually progressive and terminates finally in complete rigidity of the spine, which is bent into a long kyphosis most marked in the upper dorsal region, the lumbar lordosis being obliterated in many instances.

When the disease is limited to the spine or to the spine and larger joints, the occipito-axoid articulations are not usually involved; but in the cases of general rheumatoid arthritis, stiffness of the neck may be an early symptom.

Treatment.—The local treatment is symptomatic. The application of the cautery adds to the patient's comfort, and self-suspension at intervals may relieve the dragging sensation in the muscles. Rubber heels are of service in lessening the jar. A brace or plaster corset may be applied if the pain is aggravated by motion. It should serve also, together with the avoidance of predisposing attitudes, to prevent extreme deformity of the spine. Such protection is of great service if it is applied early in the course of the disease, especially in those cases in which it is localized, as it sometimes is in the lumbar region.

ADOLESCENT KYPHOSIS.—A form of extreme kyphosis, accompanied by stiffness and discomfort, is not infrequently seen in adolescence. It appears to be a static deformity induced by overwork. It can hardly be classified with spondylitis deformans, although there may be some difficulty in distinguishing between the two. The treatment is, if possible, prevention in avoiding predisposing postures and in strengthening the muscles. In more advanced cases, forcible correction after the Calot method, followed by support, massage, and exercise, may be of service.

The kyphosis of old age is a familiar deformity that does not require special mention.

OSTEITIS DEFORMANS.—Osteitis deformans is described elsewhere. It is a general disease characterized by hypertrophy and softening of the bones. The deformity of the spine is similar to that of spondylitis deformans, but the local discomfort is far less marked.

THE NEUROTIC SPINE.—This affection is far more common in adolescence and adult life than it is in childhood, and in females than in males. The subjects are usually of a nervous or neurasthenic type, often overworked and physically depressed. In certain instances, however, the exciting cause appears to be direct injury. The patient usually complains of a dull pain in the back of the neck, or in the lumbar or sacral region, of a constant tired feeling, and not infrequently of sharp neuralgic pain localized about a certain point in the spine, often the vertebra prominens. The contour of the spine may be normal, but there is usually a well-marked tendency toward a forward droop, the curve of weakness. A common symptom of the neurotic spine is the extreme local tenderness, or hyperæsthesia of the skin over certain spinous processes. Thus, if one passes the finger gently along the spine the patient will often shrink or cry out when the sensitive point is reached. The pain is usually localized about the spine, and there is no limitation of movement or especial discomfort on motion. The symptoms are distinctly subjective, thus differing from those of actual disease.

Treatment.—The treatment of the neurotic spine must include, of course, the general condition of the patient. Locally, a light back brace or a long corset, reinforced with steel bands, adds to the comfort of the patient. The application of the cautery lessens the local sensitiveness. Massage and exercises may be employed with advantage. Complete recovery is usually long delayed.

THE HYSTERICAL SPINE.—The hysterical spine is usually classed with the neurotic spine. The local subjective symptoms may not differ particularly from those of the neurotic spine, but in certain instances actual deformity may be present. This is usually exaggerated lateral distortion of the lumbar region. This deformity may appear after injury, but, except as a possible cause of a particular manifestation of the mental condition, it is usually apparent that injury cannot explain the symptoms or the deformity.

Treatment.—The local treatment is similar to that of the neurotic spine.

PAIN IN THE LOWER PART OF THE BACK.—Pain, discomfort, and weakness are sometimes symptomatic, being caused by disease or displacement of the pelvic or abdominal organs. Similar discomfort is a common symptom among overworked women. It is usually present also whenever the lumbar lordosis is exaggerated, as a compensatory deformity for dorsal Pott's disease, or because of flexion of the thigh after hip disease.

The *treatment* must be directed to the conditions of which it is a symptom.

Pain and weakness in the lumbar region may be induced by strain or other injury. In such instances it is usually increased by sudden motion or overexertion, and it may be persistent and disabling. Such cases are often classed as chronic lumbago. The cause is apparently strain of the deep ligaments or muscles of the spine, but the symptoms may be exaggerated, doubtless in certain instances by gout, rheumatism, or other disease of this character.

When motion causes pain and when the symptoms are persistent, support in the form of a back brace is indi cated, the Knight brace or plaster corset being convenient forms. During the more acute stage the cautery, followed by the application of intersecting straps of adhesive plaster covering a wide area, will often relieve the pain. Later, massage, electricity and the like, may be of service.

FIG. 4423.—Sciatic Scoliosis.

SPONDYLOLISTHESIS.—Spondylolisthesis, or exaggerated lordosis, is a deformity in which the body of one of the lower lumbar vertebræ, most often the fifth, is displaced forward and downward. The displacement is usually accompanied by distortion of the affected vertebra. The spinous process remains in its normal position, while the laminæ become elongated or separated from the displaced vertebral body. Spondylolisthesis was first described by Killian in 1854 and more recently by Neugebauer in 1890.

The ordinary causes are congenital malformation, injury, and possibly disease of the lumbo-sacral articulation. Lane states that slighter degrees of the deformity are often observed among laborers. The effect of the displacement is to exaggerate the lumbar lordosis and to increase the prominence of the sacrum and of the iliac crests. The deformity is most often seen in women, causing no particular symptoms; in fact, its chief interest lies in its effect upon childbirth.

Treatment.—Support may be required if the symptoms indicate it. In the slighter grades of deformity a strong corset reinforced by steel bands is efficient.

DEFORMITY OF THE SPINE SECONDARY TO SCIATICA.—Persistent sciatica often induces a change in the attitude and contour of the spine. As a rule the patient habitually inclines the body away from the painful part, in order to relieve the limb from weight, and bends the body slightly forward to relax the tension on the sensitive nerve or plexus of nerves. Thus the pelvis on the affected side projects, there is a lateral lumbar convexity toward the opposite side, and often the normal lumbar lordosis is lessened or lost, so that the final result may be a permanent lateral curvature together with a flattening of the lumbar region. If the sciatica is a symptom of a more widespread neuritis of the lumbar plexus, muscular weakness and muscular spasm may cause variations in the typical attitude, but this is unusual.

Aside from the direct treatment of sciatica support may be indicated if movements of the spine aggravate the pain. This is always indicated when there is danger of persistent distortion. The patient should be suspended and corrective jackets applied at frequent intervals. As the attitudes and symptoms described may be caused by disease or injury of the sacro-iliac articulation, this region should in all instances be carefully examined.

Neuritis of spinal nerves in other regions of the spine may cause symptoms of reflected pain and local sensitiveness. These are increased by motion, and a certain amount of deformity, similar in character to that due to sciatica, may be present.

The treatment is similar to that indicated for the former affection. *Royal Whitman.*

SPINE, SURGERY OF THE.—It is essential, before we enter upon the study of the surgery of the spine, that we should have a fairly thorough acquaintance with the most salient points in its anatomical construction.

The spinal column is not a straight structure, but presents a series of curves corresponding to its various portions. The cervical portion presents a concavity; the dorsal a convexity; the lumbar a concavity; while the sacrum and coccyx are slightly convexed. On account of its being made up of a large number of vertebræ, which are separated from each other by intervertebral substance and are held together by elastic ligaments and muscles, it presents a flexuous and flexible column, capable of a considerable degree of motion, without injury either to its muscles or ligaments or to the spinal cord itself. The spinal canal is about twenty-seven inches in length, larger in the neck and loin where it presents a rather triangular shape, and narrower and more nearly round in the remaining portions of the canal. It is also to be remembered that the spine has a slight lateral curvature, the convexity of which is toward the right side; an exception to this rule exists in left-handed individuals.

The spinal cord is seventeen or eighteen inches in length and occupies only about two thirds of the canal—hanging loosely in it and not by any means filling up the whole contour of the canal. It extends from the upper border of the atlas to the lower border of the first lumbar vertebra, at which point it terminates in a slender filament of gray substance, known as the filum terminale. The spinal cord is vested by three membranes: the dura mater, the arachnoid, and the pia mater. The dura mater is separated from the spinal canal by loose areolar tissue and a plexus of veins—this membrane being a continuation of the one which surrounds the brain. Special attention should be given to this plexus of veins, as in many injuries of the spinal column these veins are ruptured by hyperextension, thus forming clots of blood, which impinge upon the spinal cord, producing symptoms of paralysis. Attention is also to be paid to the fact that the dura mater is not adherent to the spinal canal, which has its independent periosteum; nor does the dura mater send any of its prolongations into the fissures of the cord as occurs in the brain. The arachnoid is a continuation of the same membrane that surrounds the brain, and is connected with the spinal nerves, so as to form a sheath for them as they pass into the intervertebral foramina. The outer surface of this membrane is connected with the dura mater to a limited extent, thus leaving a considerable space, known as the subdural space, while the inner surface is connected with the pia mater by slender filaments of connective tissue. The inner surface of the arachnoid is separated from this membrane by a considerable interval known as the subarachnoidean space. The pia mater covers the entire surface of the cord, being intimately adherent to it, forming its neurilemma and sending a process into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves and invests the nerves themselves.

There are thirty-one pairs of spinal nerves divided according to the corresponding regions of the spinal canal. In the cervical region there are eight; in the dorsal, twelve; in the lumbar, five; in the sacral, five; in the coccygeal, one. A spinal nerve arises by two roots, the anterior or motor root and the posterior or sensory root. We should bear this latter division in mind, as pressure upon the anterior root in any region will produce loss of motion or paralysis in that region where the nerve is distributed, while pressure only upon the posterior root will cause loss of sensation or anæsthesia in the part to which the nerve is distributed. Our attention is also called to the fact that the roots of the spinal nerves from their origin in the cord run obliquely downward to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine and being greater in the lower than in the upper portion.

Diseases and injuries of the spine may be classified under two heads—congenital and acquired. Under the first of these divisions occurs spina bifida, while under the latter we have the following classification: First, pathological changes produced by disease, and secondly, those produced by traumatism.

Spina Bifida.—Spina bifida, or hydrorrhachis, is a congenital deformity due to the non-development of the posterior vertebral arches, thus leaving an aperture through which the membranes protrude, this condition resembling hernia as seen in other portions of the body. The varieties of this affection are known as meningocele, where the contents of the sac are composed of the spinal membranes only; meningomyelocele, where the contents of the sac consist of the cord and its membranes; and lastly syringomyelocele, where the central canal of the spinal cord is dilated, thus forming the tumor. The tumor varies from the size of a small cherry to that of an adult's head, and occurs most frequently in the lumbar and sacral regions, as these portions of the spinal column are later in their development than those in the upper regions. The shape is usually round and the surface smooth; at times there is, in the median line, a furrow which presents a pit-like depression above and below. The tumor occasionally is covered with skin, either of a red color or normal in aspect, but thin and translucent; while in other cases there is an absence of skin altogether, the outside covering being derived from the dura mater. It is very important that this affection should be correctly diagnosed, and in most cases this can readily be done. The affections simulating spina bifida may be mentioned as lipomata, and dermoid cysts or other varieties of cysts in this locality. A large per cent. of children affected by this condition die soon after birth It is a congenital

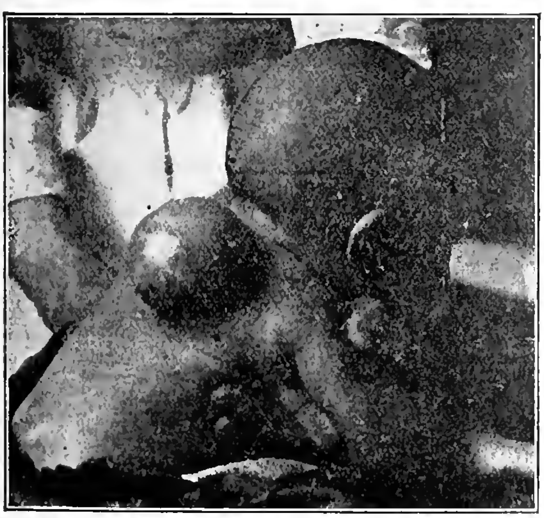

FIG. 4424.—Case of Spina Bifida; Showing the Sac before Operation.

trouble and always occupies the central position of the canal, and its fluid communicates with the fluid of the brain. Pressure upon the tumor diminishes it in size and promotes tension of the fontanels, and, when continued for any given length of time, it is followed by stupor or convulsions. By an examination around the base of the tumor, the outer lining of the bony partitions of the spinal canal can be made out, and by the use of a hypodermic syringe it is possible to withdraw a small quantity of fluid—cerebrospinal fluid, as will be found upon examination. Should the case prove to be a dermoid cyst, or cyst of any other kind, or a lipoma, all of these symptoms will be found wanting.

FIG. 4425. The Same Case as that represented in Fig. 4424; Showing the Results of the Operation.

The treatment of spina bifida may be divided into palliative and operative. In the palliative treatment, pads of absorbent surgeon's wool or gauze saturated with lanolin are applied, and gentle pressure used, either by the roller bandage or by a properly applied apparatus. The sac is sometimes enveloped with a solution of collodion, the purpose being to constrict the sac and thus diminish the bulk of the tumor.

Among operative measures, one plan is to draw out a small quantity of fluid at a time, either through a puncture or by an aspirator (a very small quantity of the fluid being drawn off at a time, say about ten or fifteen drops), and then, after sealing the opening with collodion, to apply slight pressure over the sac. This plan is to be repeated every twenty-four or sixty hours, depending largely upon the symptoms which develop. When an incision is made at the side of the tumor, it must always be in an oblique direction, and every precaution must be taken to make the parts perfectly aseptic.

Besides evacuating the contents of the tumor, injections of iodine or of alcohol are sometimes made into the sac. This treatment, however, is very unsatisfactory, as the majority of cases thus treated prove. On account of the many fatal terminations which have occurred as a result of this mode of treatment, a complete excision of the sac has been resorted to. The sac is first opened and its contents evacuated, and then, if the nerves and filaments of the cords are found in it, they are pushed back into the spinal canal and the sac ligated. If the tumor is covered with skin, an elliptical incision is made on each side of the growth, the two flaps are dissected down to the neck of the tumor, the membrane is punctured and the fluid let out, the sac is opened as suggested above, and a sufficient amount of it cut away to approximate the edges closely. Great care should be taken not to injure the nerves or the cord if they appear in the tumor; they should be carefully replaced in the spinal canal, and the edges of the membrane should be closely approximated by a separate row of catgut sutures and the skin flaps brought together by silk or silkworm gut sutures. If after opening the sac the nerves are found to be adherent to the posterior part of the sac, they should be separated by careful dry dissection, and pushed back into the spinal canal. Should the tumor be devoid of skin, it is best to borrow some skin from the adjacent region and make a skin graft over the surface of the wound left by such transfer.

Should the opening be a large one, bone grafts may be taken from the adjacent bone, or borrowed from an inferior animal, the chasm being thus filled up, or, as has been suggested by a recent writer, large silver wire may be placed across the opening, thus preventing the hernia from again making its appearance.

It is unnecessary to say that the strictest asepsis should be enforced in this operative procedure.

Dermoid cysts, lipomatous tumors, and cystic tumors of other varieties occurring in this region should be dealt with in the same manner as in other portions of the body.

Among the acquired diseases which call for surgical treatment may be mentioned, first, the various curvatures of the spine. As these have already been treated under other heads, I may pass at once to the consideration of certain features in the treatment of Pott's disease. (The subject, as a whole, is discussed under the title *Spine, Tuberculous Disease of the*.) Should pressure of the cord be present, in this disease, an operation for relieving this pressure by removal of laminæ should be performed. If fluctuation exists, denoting the presence of pus, the cavity should be evacuated by an ordinary trocar and cannula or an aspirating needle. Should the pus not be withdrawn as readily as expected, on account of broken-down tissue, the removal of this tissue can be facilitated by the use of an aseptic wire bent in the shape of a small hook. After the abscess cavity has been completely evacuated, it is advisable to inject a ten-per-cent emulsion of iodoform in glycerin. While iodoform does not act as a germicide, it has been satisfactorily demonstrated that it retards the growth of the tubercle bacilli. Numerous trials of this method have fully convinced me of its great utility in materially cutting short the disease. About one-half drachm of the emulsion is injected the first time, and if no unpleasant symptoms result this quantity, if necessary, may be increased at the next application. An interval of about seven or eight days should occur between the injections. When the needle is withdrawn, the puncture in the skin is closed with collodion or liquid celluloid, and a compress and bandage are applied to the part so as to cause the walls of the abscess to collapse. As the last step, the patient is placed in bed, slight extension and counter extension are instituted, and absolute rest is enjoined. If the first injection proves beneficial, it will seldom be necessary to employ more than two or three of them. It is to be borne in mind that iodoform is not efficacious in cases of mixed infection, but only in those cases in which the disease is produced by the tubercle bacillus. When the disease occurs in childhood and when early diagnosed, the deformity can be entirely or almost entirely corrected and the spine made to assume its normal position. The details of the method which it is necessary to pursue will be found in the following article.

Contusions or Sprains of the Spinal Column.—On account of the complex structure of the vertebral column, and of the large number of veins and nerve filaments which issue from the spinal cord contained within it, direct injuries inflicted upon this column may at times be followed by great loss of function. The symptoms presenting themselves depend very largely upon the degree of injury that has been sustained; this may be slight in extent, producing only temporary stiffness or soreness over a limited area; or it may, on the other hand, be more serious in character, as when the ligaments of the spine are either partially or completely torn away. Such serious results are observed in runaway accidents and after railroad collisions. When the ligamenta subflava are involved, severe hemorrhage of an extradural character may occur and paraplegia result; this, however, in many cases, is only of short duration, the extravasated blood being absorbed and recovery being the rule. When examined externally, the injured portion of the spine presents either a slight or considerable swelling, together with great tenderness and pain. In some cases the pain is so great at the point of injury that the patient involuntarily immobilizes the spine and in this way avoids any rotation or flexion of the column, the slightest degree of which often throws him into spasms. It is of the utmost importance in the examination of these cases that a correct diagnosis be made between contusions and fractures or dislocations of the spine. Cases of severe contusions present symptoms closely analogous to those of a fracture or a dislocation, such as partial or complete paralysis, corresponding to the seat of injury, and produced by either extra- or intradural hemorrhage. These symptoms of paralysis, however, are transient, readily passing away after absorption of the effused blood. In some cases in which hemorrhage has been severe the symptoms are prolonged, and the diagnosis between contusion, fracture, and dislocation is made out only by a careful examination of the bony canal and the discovery of signs which are revealed after the swelling has sufficiently subsided.

FIG. 4426.—Fracture of the Spine due to a Fall from a Height of Eleven Feet. Picture taken ten weeks after the occurrence of the accident. (Courtesy of Dr. Royal Whitman, of New York.)

The treatment for contusions of the spine is conducted upon general principles, namely, rest, position, etc.: pain is relieved by hot or cold applications, or by the administration of anodynes if the pain is severe. All friends and acquaintances of the patients are to be kept out of the room, light must be excluded from the eyes, and every precaution must be taken for relieving them of anything of an irritative character.

One of the unfortunate symptoms following contusion is great irritability and nervousness. As soon as the swelling subsides, ointments such as brown citrine or compound iodine are to be freely rubbed over the part. To allay irritability and nervousness, chloral hydrate, bromide of potassium, or hydrobromate of hyoscine should be administered.

Fractures of the spine are quite rare as compared with fractures in other portions of the body. The portions of the column most frequently fractured are the cervical and dorsal regions, while the lumbar and sacral are very seldom the seat of this injury. The two vertebræ which are most commonly broken are the fifth and sixth cervical. Fractures of the cervical vertebræ terminate more frequently in death than do fractures of any other portions of the vertebral column. These fractures, as a rule, occur during middle life and are more frequent in the male than in the female, this being due to the fact that the occupation of the male renders him much more liable to these accidents. These fractures occur in the body and arches, and there is every reason to believe, from statistics on this subject, that in the great majority of them they occur much more frequently in the arches than in the body of the vertebra. When these fractures occur, the majority of them are due to forcible flexion of the spine, the head and neck approximating, or the chest and the pelvis. Such injuries are apt to be produced by the caving in of an embankment, by a fall from a high scaffold, or by the doubling of the body in passing through a tunnel, as has been exemplified in several cases that have come under my personal observation. Whenever the injury is of such a nature as to produce a fracture in the vertebræ, it is always accompanied with considerable laceration of the muscles and ligaments, and often with hemorrhage, which may be extradural or subdural. At times there is crushing of the bodies of the vertebræ, with greater or less displacement.

Fracture of the spine in the middle region without displacement may cause angular deformity, and, when proper support has been neglected, symptoms of pain and weakness similar to those of Pott's disease may persist indefinitely (Fig. 4426.)

The symptoms of fracture of the vertebræ are generally pronounced; they consist of deformity, crepitation, and partial or complete paralysis below the seat of fracture. There is usuallygreat shock attending these injuries. In fracture of the vertebræ in the lower lumbar, sacral, and coccygeal regions, on account of the absence of the spinal cord, we have very seldom either a complete or a partial paralysis, but all the other signs of fracture are generally present.

The prognosis of fracture of the spine, especially when it occurs in the upper spinal region, is very unfavorable; if the patient should recover from the shock attending such injuries, he is very likely to be paralyzed the rest of his days.

Gunshot fractures of the vertebræ partake of the character of a compound fracture, and consequently are frequently complicated with infection and thus make the prognosis much more unfavorable.

In the treatment of fractures of the spine, the patient should be placed in a recumbent position and extension and counter-extension should be maintained. Gentle pressure should be made in such a manner as to relieve and correct the deformity. An air- or water-bed is preferable to any other contrivance for placing the patient upon. If it should be impracticable to obtain such a bed, a short hair mattress made perfectly smooth should be procured; but under no circumstances should the patient be placed upon a feather mattress. Extension can be maintained by applying Buck's extension apparatus to both legs, the weight and pulley being placed at the end of the bed, and counter-extension being maintained by a leather cap which fits the head and comes under the chin. In many cases this counter-extension can be improved by having the foot of the bed elevated higher than the head. If more than one vertebra has been injured, the parts may be held in position, and probable deformity prevented, by placing compresses of surgeon's wool on each side of the injury and holding them in place by adhesive strips. It is found necessary in almost every case to catheterize the patient, and great attention should therefore be paid to the toilet of the bladder, so as to keep this organ from chronic inflammation. The patient should be kept scrupulously clean, with plenty of fresh air, and a simple but nutritious diet should be prescribed. In quite a number of cases it will be discovered that a portion of the lamina is pressing upon the cord, and should this be recognized, an operation known as laminectomy should be performed. On account of the fatality of fractures of the spine and the helpless condition in which many patients are left from the effect of this injury, surgeons have felt themselves warranted in taking any steps, it matters not how heroic, for the purpose of saving or at least benefiting the injured. For this purpose, in recent years, the operation of laminectomy has been devised. It is true that the operation has not furnished as brilliant results as could be desired, yet some of the remarkable recoveries that have been obtained by this operation have led many surgeons to believe that, should the operation be performed early enough, many lives might be saved which now are lost, and new laurels added to surgery. I am of the opinion that the delay in resorting to this operation has led to degenerative changes in the cord, and is responsible for the many unsuccessful issues; I would therefore urge an immediate operation in every case of fractured lamina. In a number of cases, owing to the amount of swelling, it is impossible for a surgeon to tell exactly what the conditions are until he has cut down upon the vertebræ and examined them. Aseptic surgery has made this possible, and when in doubt the surgeon should cut down upon the vertebræ and thus give the patient every opportunity for a complete recovery. The operation is performed in the following manner: The patient is placed with his face slightly downward and with a small hard pillow under the lower ribs, thus giving the spinal column a gentle curve; the parts are cleansed and made thoroughly aseptic, and an incision is made of from three and one half to four inches in length, parallel with the tips of the spinous processes; the middle point of this incision corresponding with the seat of fracture. The muscular structures are now detached from the sides of the spinous processes, and the posterior surface of the lamina is brought into view. With a periosteotome the periosteum is separated from the bone; a procedure which should be carried out with great care, so as to preserve as much of the periosteum as possible. The wound is now held open by retractors and, if there is any hemorrhage, it should be entirely controlled, either by hæmostatic forceps or by the application of hot, sterilized water. The spinous processes are divided by a strong pair of bone forceps, thus enabling the operator to gain a perfect view of the laminæ. The laminæ are then either simply elevated or bit off by a pair of rongeur forceps. The membrane and spinal cord are now inspected. Should the dura mater show by discoloration the presence of blood, it should be incised, the imprisoned blood evacuated and the hemorrhage controlled, and the parts thoroughly irrigated with either a saline solution or sterilized hot water. After the cord and nerves have been carefully examined, cleansed, and placed back in the best possible condition, the dura mater should be adjusted and its edges brought together by interrupted catgut sutures. The muscular structures are sutured by the same material and the skin approximated by silk or silkworm sutures. After the operation, the patient should be placed on an air- or water-bed, shock should be combated, and every detail in the after-treatment should be carefully carried out.

Dislocations of the Vertebræ.—In the great majority of cases dislocations are associated with fractures, but, in a few instances which come under the surgeon's observation, the dislocation is entirely uncomplicated with fracture. These injuries are either produced by forced flexion or by hyperextension, and may be either unilateral, bilateral, or complicated with hemorrhage in the cord. The vertebræ that are more prone to dislocations are the last dorsal, first and second lumbar, and the last cervical. With all of these dislocations we have either a partial or a complete laceration of ligaments and muscular structure, together with such complications as rupture of blood-vessels, injuries to nerves, and laceration of the intervertebral discs. As a rule, these discs are readily recognized, as they show a very great displacement from their normal position. Dislocations are distinguished from a fracture by an absence of crepitation or preternatural mobility. The great weight of authority is against any effort to reduce these dislocations, as by so doing it is feared that a more serious complication may arise and the patient lose his life; yet in some cases I believe it is the duty of the attending surgeon to attempt a reduction. This may be effected by traction, aided by flexion and rotation. It is the duty of the surgeon, before proceeding with this method, to inform the patient's relatives and friends of the great danger which accompanies this undertaking, and to obtain from them their sanction before he resorts to this measure.

Hemorrhage of the Cord.—This may be either extradural, subdural, or intraspinal. The symptoms following extradural hemorrhage are at first somewhat akin to those of laceration of the muscular tissue surrounding the spinal column; but later on, owing to the extravasation of the blood, great pain is felt in the region involved, and still later, in some cases, symptoms of paralysis supervene. In the subdural variety the pain and paralysis occur much earlier and are then followed in almost every case by paralysis. On the other hand, in the intraspinal variety, symptoms of paralysis come on immediately, thus simulating fracture or dislocation of the spine. In some cases of hemorrhage of the spinal cord, where the hemorrhage is slight, absorption may take place and an ultimate recovery ensue. In other cases in which the symptoms are prolonged, the patient, instead of getting better, gradually grows worse; in which event it is the duty of the surgeon to operate and evacuate the blood or remove the clots that have formed.

Abscess of the Spinal Cord.—In all cases of abscess of the spinal cord, when diagnosed, an operation for the speedy evacuation of the pus should be performed and drainage established.

Tumors of the Cord.—These tumors are either of a benign or of a malignant type, and when recognized they should be dealt with in the same manner as are similar tumors when found in the brain. *Paul F. Eve.*

SPINE, TUBERCULOUS DISEASE OF THE.—(Synonym, Pott's disease.) Pott's disease is a chronic destructive process that affects the bodies of the vertebræ, the anterior and weight-supporting portion of the spinal column. As the disease progresses the part of the spine above the weakened point sinks downward and forward, throwing into relief the spinous processes at the seat of disease. Thus an angular posterior projection is the

1. 2.

FIG. 4127.—Spinal Lesions in Pott's Disease. 1, Disease in two distinct regions of the spine; 2, a section of the spine showing the production of angular deformity.

characteristic deformity of Pott's disease, or rather of any process attended by local destruction of one or more of the vertebral bodies. If one vertebral body is destroyed, the projection is sharp and well defined; if several are involved, it will be less angular; and if one side of a vertebral body breaks down, there may be a slight lateral distortion as well.

The size of the deformity and its effect upon the individual depend in great degree upon its situation. If it is at either extremity of the spine the deformity is small, because so little of the spine is affected compared with that which remains free from disease. Thus, angular deformity in the upper cervical region simply shortens the neck, and disturbs the poise of the head. In the lowermost region it shortens the trunk and induces a peculiar attitude, but in either case the posterior projection or "hump" is slight; but when the middle of the spine is involved the opportunity for deformity is great and the entire spine may enter into the formation of the kyphosis.

PATHOLOGY.—The first indication of disease is usually found in the anterior part of a vertebral body beneath the longitudinal ligament. From this point the infected granulation tissue, following the course of the blood-vessels, invades and destroys the adjacent spongy tissue. In other instances the disease may begin in several minute foci in the interior of a vertebral body near the upper or lower epiphysis. These, coalescing, gradually enlarge, forming a cavity; collapse follows and the deformity appears. Less often the disease advances beneath the anterior ligament as a form of tuberculous periostitis, without implicating deeply the substance of the vertebral bodies. The posterior part of the spinal column usually remains free from disease, unless it comes into direct contact with it.

The course and outcome of the disease depend upon its character. If the area of primary infection is limited, the local resistance may check its further progress and cure without deformity may follow. In other instances, although the area of active disease is small, it continues to progress and the deformity slowly increases, although unaccompanied by pain or by constitutional symptoms. In the majority of cases, however, the tuberculous granulations advance rapidly, destroying the bone or other tissues with which they come into contact. The usual retrograde metamorphosis to cheesy degeneration follows, and then very frequently liquefaction or abscess formation takes place.

In characteristic cases that come to autopsy during the progressive stage of the disease, one finds, on dividing the thickened tissues in front of the spine, a cavity the walls of which are lined with tuberculous granulations in various stages of degeneration and containing puriform fluids. The adjoining vertebral bodies present a worm-eaten appearance, and one or more of them is partially destroyed. Small fragments of necrosed bone and "bone sand" may be present, together with larger masses of degenerated tissue; less commonly sequestra of considerable size may be found, loose or embedded in the diseased area.

As the disease progresses it may force its way into the vertebral canal and press upon the spinal cord, involve its coverings, and cause paralysis of the parts below. Such a complication is more frequent when the disease begins in the centre or posterior portion of a vertebral body. In such instances the paralysis may precede the deformity. Pressure on the cord may be caused also by an abscess or a projecting fragment of bone. The calibre of the spinal canal may be lessened also by the pressure of the superincumbent weight upon the softened and thickened tissues at the seat of disease, but as a rule its capacity is not directly lessened by the characteristic angular distortion. In fact, pressure paralysis more often complicates cases in which the deformity is moderate or slight in degree than those in which it is extreme.

In rare instances tuberculous disease may appear in two regions of the spine simultaneously, but it usually begins in one or two adjacent vertebral bodies, one or both of which are partially destroyed. From this point the disease extends in either direction, and in ordinary cases the final area of deformity and rigidity shows that from three to six bodies are more or less involved before a cure is established.

At all stages of the disease resistance to its progress and local efforts at repair are evident in the affected parts. This is accomplished occasionally by contact and solid union of the adjoining surfaces of softened bone, but this is possible only when the area of the disease is small. If several bodies are destroyed there is usually backward displacement of the upper segment of the spine as it sinks downward. Thus the anterior surface of one or more of the bodies of the upper segment may be apposed to the upper surface of the lower body. In such instances the ankylosis is in part fibrous, in part cartilaginous, and in part bony. This may include the articular processes, the pedicles and laminæ; in fact, ankylosis may be established here before repair has advanced appreciably in the anterior portion of the column.

Cure may be complete, no vestige of the disease remaining; or the diseased products may undergo calcareous degeneration and may be enclosed in newly formed tissue. In other instances the disease is simply quiescent, and may show its presence from time to time by recurrent symptoms of discomfort, by abscess formation, or even by paralysis many years after apparent cure.

ETIOLOGY.—The etiology of tuberculosis of the spine does not differ from that of other bones; the subject is considered elsewhere.

Relative Frequency.—Tuberculosis affects the spinal column more frequently than it does any other single bone or joint. This point is illustrated by the statistics of tuberculous disease treated in the out-patient department of the Hospital for Ruptured and Crippled during a period of fifteen years: Tuberculosis of the spine, 3,207 cases; hip-joint, 2,230 cases; other joints inclusive, 2,408 cases.

Age.—Pott's disease, although far more frequent in the middle period of childhood (from the third to the tenth year), may occur at any time from earliest infancy to extreme old age.

STATISTICS FROM WHITMAN'S ORTHOPEDIC SURGERY.

	Cases.	Per cent.
Less than one year	38	3.1
Between one and two years	176	11.2
Between three and five years	627	50.2
Between six and ten years	234	18.3
Between eleven and twenty years	89	7.2
Between twenty-one and thirty years	43	3.5
Between thirty-one and fifty years	31	2.6
Over fifty years	11	.8

The youngest patient was two months old, the oldest seventy-one years.

Sex.—Sex exercises comparatively little influence upon the liability to disease of this region. In 3,822 cases 53.2 per cent. were in males and 46.8 per cent. in females (*loc. cit.*).

The Situation of the Disease.—The dorso-lumbar section of the spine is most often affected. Cervical disease is comparatively infrequent.

In the series of 1,355 cases (*loc. cit.*) the attempt was made to locate the origin of the disease by the most prominent spinous process in the tracing. The following are the conclusions:

Cervical.		Dorsal.		Lumbar.		Lumbo-sacral.	
First,	3	First,	26	First,	94	13	
Second,	3	Second,	43	Second,	96		
Third,	15	Third,	42	Third,	64		
Fourth,	20	Fourth,	46	Fourth,	57	No deformity.	
Fifth,	13	Fifth,	49	Fifth,	6	Cervical,	2
Sixth,	22	Sixth,	76			Dorsal,	31
Seventh,	24	Seventh,	82		317	Lumbar,	22
		Eighth,	97				
	100	Ninth,	92				55
		Tenth,	110				
		Eleventh,	71				
		Twelfth,	120	Disease in two regions of the spine, 16.			
			854				

From these statistics, which do not differ essentially from those reported by others, it appears that the disease is much less common in the cervical than in the dorsal region. This may be explained by the greater strain to which the middle and lower part of the spine is subjected, as well as by the relatively larger proportion of cancellous tissue which offers the opportunity for infection.

PROGNOSIS.—Pott's disease is the most serious of all the tuberculous affections of the bones and joints, because of the relative importance of the structures directly and indirectly implicated. Prognosis must include also the indirect influence of the deformity. In the typical "humpback" deformity the contents of the thorax and abdomen are necessarily compressed, the blood vessels are distorted and the calibre of the aorta is thereby often much diminished, respiration is made difficult, and the circulation is impeded. As a consequence the heart is usually hypertrophied or dilated, and valvular insufficiency is not infrequent. Thus the vital functions which are carried on at a disadvantage even under favorable conditions become impossible under the added strain of unfavorable surroundings, overwork, or disease. It is a matter of common observation that few of those who are markedly deformed reach old age. On the other hand, it may be assumed that slight deformities, or those which do not as directly interfere with the vital functions, exercise but little influence upon the future well-being of the patient. This emphasizes the importance of early diagnosis and efficient treatment.

The direct mortality of Pott's disease cannot be accurately estimated, but at least twenty per cent. of all patients die during the progress of the disease and within a few years after its onset, from causes directly or indirectly dependent upon the local lesion. Some of these die from general dissemination of the tuberculous infection and tuberculous meningitis; some from exhaustion following septic infection or from amyloid degeneration and exhaustion dependent on long-continued suppuration; some from tuberculosis of the lungs, and many from intercurrent affections that are fatal because of the devitalizing influences of the disease and its complications.

SYMPTOMS.—The most positive sign of Pott's disease is deformity. At an early stage of the process there may be but a slight irregularity in the contour of the spine, and if several adjacent vertebral bodies are affected the projection may be somewhat rounded in outline. But as compared with other deformities of the spine, that of Pott's disease is characteristically angular, because its cause is loss of substance.

This angular deformity was once thought to be essential for diagnosis, but it is simply the result of disease that may have existed for months, a disease whose presence may be detected long before it reaches the destructive stage.

The spine is the most important support of the body, an elastic column that accommodates itself to every movement of the trunk and limbs. The early symptoms of a destructive disease must be therefore pain and functional disability. The spine also contains the spinal cord, from which branch the nerves that supply the organs and members of the body, and in certain instances the sudden onset of paralysis due to extension of the disease backward might occur early in the process. Or, again, abscess, one of the common accompaniments of tuberculous disease, might, because of its size or situation, become the most noticeable symptom.

These are symptoms that may be misleading, and it is well, therefore, to consider them apart from those that indicate the primary effect of the disease upon the spine considered as an elastic support. These direct symptoms usually precede and always accompany the secondary or complicating symptoms, and upon them the diagnosis depends.

The primary and diagnostic symptoms of Pott's disease may be classified as follows:

(*a*) Pain.
(*b*) Stiffness.
(*c*) Weakness.
(*d*) Awkwardness.
(*e*) Deformity.

The *pain* of Pott's disease is not usually localized at the affected vertebræ nor is it accompanied by sensitiveness to pressure or infiltration and swelling of the overlying tissues, as is usually the case when other bones are involved; for the vertebral bodies are within the trunk, almost as far from the spinous processes as from the anterior surface of the body.

Thus sensitiveness to direct pressure is unusual, and palpation, except in the cervical region, is of little diagnostic value.

The pain of Pott's disease is not localized, because the nerve filaments that supply the bodies of the vertebræ are insignificant parts of nerves that are distributed to distant points—to the head, to the limbs, to the front and sides of the body, and to these parts the pain is referred. Thus "earache" or "stomachache" or "sciatica" may be symptomatic of Pott's disease of the different regions of the spine. This pain is by no means constant; it is rather occasional, induced by jars or by sudden unguarded movements. Often at night when muscular protection is relaxed, sudden movements during sleep cause discomfort or pain and the child moans, or is restless, and sometimes wakens with a cry—"night cry."

Stiffness of the spine is in some degree voluntary, in that the patient adapts himself to the disease and avoids, if possible, strain and jar, but the essential stiffness of Pott's disease is caused by the involuntary muscular tension and contraction of the muscles about the seat of disease. The degree of muscular spasm varies with the sensitiveness of the diseased tissues; thus it may fix the spine, or it may limit only the extremes of motion. Reflex muscular spasm precedes deformity and continues until a cure is established; it is therefore the most important of the diagnostic symptoms of Pott's disease.

A destructive disease of the most important support of the body it is a direct as well as an indirect cause of *weakness*; the younger the patient, the more apparent is this symptom which is shown by the "loss of walk," the refusal to stand, or the instinctive desire for support at an early stage of the disease.

Awkwardness.—Pain and weakness and rigidity of the spine induce changes in the habitual attitudes and movements of the patient that are often almost diagnostic of the disease and of the part of the spine involved.

The deformities of Pott's disease may be classified as—Bone deformity, muscular deformity, compensatory deformity.

The characteristic angular projection due to destruction of bone has been described already.

Muscular deformity is the distortion due to muscular spasm or contraction. Wry-neck, symptomatic of cervical disease, and psoas contraction, a common accompaniment of disease of the lower region, are the familiar examples.

Compensatory deformity signifies the general effect of the local disease and local distortion upon the spine as a whole. Thus an angular projection must be balanced by a compensatory incurvation, and lateral distortion in one direction by lateral distortion in another. These secondary changes in contour often attract attention before the primary local deformity is detected.

Although angular deformity is characteristic of the disease, lateral deviation of the spine is not infrequent. It may be direct distortion at the seat of disease, caused by the destruction of the side of a vertebral body; more often, it is a secondary effect of such irregular erosion at one or the other extremity of the spine. It may be caused by muscular contraction, or it may be due to simple bodily weakness. In such instances it is a transitory distortion.

Aside from direct deformity, there is usually at the earliest stage of the disease a slight change in the outline of the spine; it no longer forms a long regular curve when the body is bent forward, but an irregularity of contour, of limitation of normal flexion, is almost always apparent.

Secondary Symptoms.—Abscess.—In the retropharyngeal space the tumor of an abscess may interfere with respiration and deglutition. In the thoracic region it may, from the physical signs, be mistaken for pleurisy or empyema, and in the iliac fossa, when accompanied by psoas contraction, it may interfere with locomotion.

Paralysis is usually one of the later symptoms, but if the disease begins in the centre or posterior part of a vertebral body it may implicate the cord before deformity appears.

Abscess and paralysis are classed as complications because they must be explained by a proper diagnosis. Their appearance is always preceded and accompanied by the essential symptoms of Pott's disease.

General Symptoms.—If the disease is active or if an abscess is approaching the surface there is usually a slight but constant elevation of the temperature, but the positive value of the symptom in early or quiescent cases is doubtful. A patient suffering from tuberculous disease of the spine usually presents the evidences of a painful and depressing affection and in many instances the appearances of inherited or acquired weakness; but these general symptoms are of comparatively little value in diagnosis.

Of the early symptoms of Pott's disease two have been noted as of especial importance—the impairment of normal mobility and the change in the contour of the spine. The contour of the spine varies considerably in the adult. It is affected by the occupation and by many other circumstances; of this the round shoulders of the cobbler or the weaver, the stoop of weakness and of old age, are familiar examples, but in childhood distinct variations from the normal contour almost always have a pathological cause. As the normal contour is the effect of the balancing of the body in the upright posture, it is evident that if the outline of one part is permanently changed, compensation for this change must be made in another part. Thus, when deformity is well marked the normal curves of the spine are often completely reversed, and even at an early stage of the disease the abnormal contour will often attract attention long before the characteristic angular projection has become apparent.

Although the spine is a flexible column that is constantly changing in outline with every movement and posture, yet the range and character of this motion vary greatly in its different parts. In the cervical and lumbar regions motion is extensive, but it is comparatively limited in the thoracic region because the intervertebral discs are thin, because of the overlapping spinous processes, and because it forms a part of the rigid thorax. It is evident that the symptoms of a destructive disease will show themselves far more quickly in those regions of the spine where motion is free than where it is slight, and that these symptoms will differ somewhat in character with the function of the part involved. Thus, in considering early diagnosis, and in fact treatment and prognosis, one should divide the spine into sections:

1. The neck part, that allows free motion of the head, ending at the third dorsal vertebra.

2. The rigid thoracic part, which includes the third and tenth dorsal segments.

3. The lower portion, made up of the two lower dorsal and the lumbar vertebræ, in which the principal movements of the trunk are carried out. One must bear in mind the distribution of the nerves because the characteristic pain is referred to their terminations, also the parts in relation to the spine at different levels that may be implicated in the disease. Thus, remembering that the symptoms of Pott's disease are in general stiffness, weakness, pain, and deformity, one will always apply these symptoms to a particular region of the spine and will picture to himself the effect of such stiffness, weakness, and deformity at this or that vertebra; the effect of an abscess in this or that situation, and the area of paralysis that might be caused by pressure on the cord at one or another level.

The Rational Signs.—The symptoms of Pott's disease vary not only with the region of the spine involved, but also with the age and surroundings of the patient.

Tuberculous disease of the spine is usually an insidious chronic affection which does not often attract attention in its incipiency. The child may cry after overexertion or injury, but at other times it may appear, to the unobservant eye, to be in its usual health. When the diagnosis is finally made, however, the parents always remember that something was "wrong" with the child, that it was fretful and disinclined to play, that it liked to lie on the floor, that it was awkward in its movements, that it was troubled by a cough or indigestion or by oppression of breathing. These symptoms, which are readily explained by the disease, do not as a rule attract attention until deformity appears.

An exact history of the case is often of importance both as to prognosis and as to treatment. For example, one should inquire if the immediate relatives of the child have suffered from phthisis or other form of tuberculosis;

also if the child has always been strong, and if recovery from the ordinary ailments of childhood was prompt or tedious, in order that one may judge of the quality of the patient. One next asks, not "How long has the child been ill?" for this is usually understood to refer to the duration of the more decided symptom, but, "When was the child last perfectly well?" Then as to the onset of the first symptoms, whether it was sharp and decided, or gradual and ill defined; and whether the symptoms were preceded by contagious disease or by injury. If there is a history of injury it should be made clear whether the injury was the direct cause of the symptoms, or if it may have simply aggravated or brought to light the dormant disease. To establish injury as the sole and direct cause of symptoms, the patient must have been well at the time of the accident, the symptoms must have followed immediately and have continued since; and, finally, the symptoms must be of such a nature as to be explained by a definite injury.

Physical Examination.—Although histories are usually indefinite and misleading, it is commonly made clear that the affection is chronic, although its course has been varied by acute exacerbations. This is the characteristic of tuberculous disease.

The diagnosis is, however, almost entirely dependent upon the physical examination. This begins on the first sight of the patient, when one notes the general condition and the actions and postures. These show the adaptation of the body to the disease, the conscious and unconscious efforts of the patient to guard the weak part from strain that induces pain and discomfort.

The object of the physical examination is to compare the part suspected of disease with the normal, and the examination must be purposeful.

When one asks the patient to pick up a coin from the floor—the popular test for Pott's disease—one employs it to test the mobility of the lower region of the spine, the region in which the motions of stooping and turning the body are carried out; remembering that such movements are often not restrained in the slightest degree by disease in the upper portion of the spine.

Such tests must not only be purposeful, but they must be adapted to the age and intelligence of the patient. The child that refuses to pick up a coin will often gather up its clothing, because it wishes to be dressed again. If it will not stoop it will usually rise if placed in the recumbent or sitting posture, which is an equally useful test. A child will walk toward its mother if placed at a distance from her. It will always turn its head toward her, and therefore voluntary motion of the cervical region may be tested by changing the mother's position, while the child is held by the examiner.

Young children who struggle and resist passive motion, if placed on the table, submit quietly when held in the mother's arms.

The most important of the early signs of Pott's disease is the peculiar stiffness due to the reflex action of the muscles. This spasm limits movement in all directions. It is always present from the beginning of the disease until consolidation is finally completed.

The muscular rigidity is most marked in the neighborhood of the disease, but it extends to a greater or less distance, according to the acuteness of the local process and the susceptibility of the patient. Even at an early stage the situation of the disease is usually shown by a slight irregularity of the spine in the centre of the area made rigid by muscular spasm, as well as by the change of contour. This change in outline and flexibility may be demonstrated by bending the patient forward. If the spine forms a long, even, regular curve, and if there be no evidence of pain or rigidity when such an attitude is assumed, Pott's disease is extremely improbable. If, on the other hand, the outline of the curve is broken, if the motion of one section of the spine is restrained by muscular rigidity, disease may be suspected, and, if other evidence of tuberculous ostitis is present, the diagnosis may be made with certainty.

By a careful physical examination one may expect to detect Pott's disease at any stage and to fix upon its location, or at least upon the point suspected of disease. One will then ask one's self if tuberculous disease of the bodies of the vertebræ of this particular region will satisfactorily explain all the symptoms of which the patient complains; if, for example, the pain corresponds to the distribution of the nerves, if restraint of function will explain the attitudes of the patient, if the change of contour is significant of a destructive process, and the like.

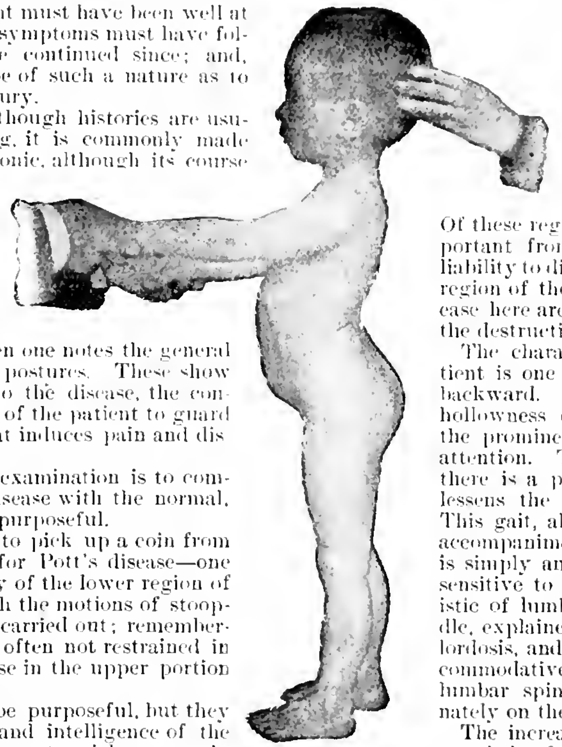

FIG. 4128.—Pott's Disease in the Lower Dorsal Region, showing Compensatory Lordosis.

The Lower Region.—As has been stated, the spine should be divided into regions according to varying function. Of these regions the lower is the most important from the standpoint of relative liability to disease, and, as it is the movable region of the spine, the symptoms of disease here are usually evident long before the destructive stage.

The characteristic attitude of the patient is one in which the body is swayed backward. Often there is an increased hollowness (lordosis) of the back; thus, the prominent abdomen may first attract attention. The walk is careful, and often there is a peculiar tiptoeing step, which lessens the jar on the sensitive spine. This gait, although most common as an accompaniment of disease of this region, is simply an evidence that the spine is sensitive to slight jars. More characteristic of lumbar disease is a peculiar waddle, explained in part by the exaggerated lordosis, and in part by the loss of the accommodative balancing motion of the lumbar spine, as the weight falls alternately on the legs in walking.

The increased lumbar lordosis so characteristic of the early stage of the disease is capable of several explanations. It is partly voluntary, the backward inclination relieving the pressure upon the diseased vertebræ. It is partly involuntary, caused by the contraction of the large muscular masses on the posterior aspect of the spine. It is in part compensatory, as the slight psoas contraction which is often present has a tendency to tilt the pelvis forward, necessitating a greater compensatory backward inclination of the body.

As the disease progresses, the lumbar section becomes straighter, and finally it may project backward in the characteristic angular deformity. Yet even after the lordosis has been changed to a kyphosis the backward inclination of the body still continues as a compensation for the reversal of the lumbar curve.

Slight psoas contraction simply increases the lordosis, but when the contraction is more extreme and persistent, the erect attitude is no longer possible. The limbs are drawn toward the body and the body is inclined forward to relax the tension. This greater contraction, which is usually symptomatic of abscess formation, is most often limited to one side. Thus the patient inclines the body somewhat forward and toward the flexed leg, "favors it," and the resulting limp is usually mistaken for a sign of hip disease. Unilateral psoas contraction of this character is, in fact, so often present when the patient is first brought for treatment, that a limp and the accompanying inclination of the body may be considered as characteristic of more advanced disease of the lumbar region.

The location of the pain depends upon the distribution of the nerves that supply the diseased vertebræ, or that

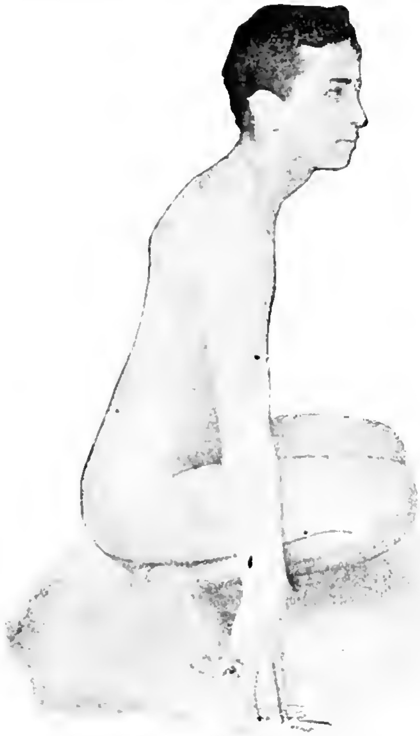

FIG. 4429.—Pott's Disease of the Lower Region before the Appearance of Deformity, illustrating the Manner of Picking up an Object from the Floor.

pass in its vicinity. It may radiate over the inguinal region or backward to the loins or buttocks, or down the front or back of the legs to the knees. Painful cramp is not infrequently a symptom, the thigh is spasmodically drawn toward the body, and the patient seizing it with both hands shrieks with pain.

Lateral inclination of the body is often present. Commonly it indicates unilateral psoas contraction, or at a later stage it may be caused by collapse or destruction of one side of a vertebral body. In other instances it is simply adaptation to weakness or pain, an attitude similar to that caused by persistent sciatica.

The effects of the stiffness, weakness, and pain are usually sufficiently apparent. For example, the child may be unable to turn in bed. If the disease is at all active, the standing is more comfortable than the sitting posture, in which more weight is thrown upon the sensitive vertebral bodies. When seated, particularly when riding in a carriage or street car, the patient often sits upon the edge of the seat, the shoulders only touching the back, while the hands rest instinctively on the seat, partially supporting the weight and steadying the spine.

Stooping, a posture that increases the pressure in the diseased vertebral bodies and which necessitates muscular tension and strain in regaining the erect position, is particularly difficult, and it is always avoided by the patient if the disease is at all acute. For example, when the child is asked to pick up an object from the floor, it either refuses or it squats on the heels or drops upon the knees instead of flexing the spine as in health. Young children having seized the object upon the floor, regain the erect attitude by pushing the body up by the pressure of the hands upon the thighs. If the child is placed upon the floor it will, if possible, seize the mother's dress, or will crawl to a chair or other object, upon which the body may be drawn up by the arms, so that the discomfort caused by muscular contraction of the back muscles may be avoided.

After this preliminary observation and examination the patient should be placed at full length, face downward, on a table, and the range of extension and of lateral motion is then to be tested by lifting the legs and swaying the body gently from side to side. One should always test for psoas contraction by holding the pelvis firmly against the table with one hand while the leg in the line of the body is gently lifted by the other. As tested in this manner the normal range of extension should allow the knees to be lifted two or three inches from the table. Slight restriction of extension of both thighs, indicating a slight degree of psoas contraction, is very common in Pott's disease, but when the restriction is marked, and especially if it be unilateral, a deep abscess may be expected. Such unilateral psoas contraction may be more clearly demonstrated by placing the child on the back, allowing the limbs to hang over the table, when the unaffected thigh will drop below its fellow.

As has been stated, in many instances the lordosis is increased, and in all cases flexion of the lumbar spine is much more restricted in the early stages of the disease than is extension. This rigidity and fixation may be demonstrated by placing the child on its hands and knees and lifting it from the floor, the trunk, instead of bending over the supporting hands, retaining almost its original contour.

Although in many instances no noticeable deformity is present, still one can almost always detect a slight fulness about the spinous processes or a slight irregularity in their line, indicating the exact seat of the disease. Strong pressure upon the spinous processes at this point may induce discomfort, and sometimes greater elasticity at the diseased area is apparent. This is, however, a test of comparatively little value.

Abscess is very commonly a complication of disease in this region of the spine, and it may be suspected when persistent unilateral psoas contraction is present in marked degree. In such cases the patient may be turned upon the side, and by deep pressure one may often detect an elastic tumor in the loin or pelvic fossa.

The diagnosis of Pott's disease, even in the early stage, is comparatively easy on careful and systematic physical examination. It is most often mistaken for some one of the following affections:

FIG. 4430.—Showing the Altitude of Over-erectness Caused by Compensation for Deformity; also abscess presenting itself in the inguinal region.

Lumbago.—This is an acute affection, usually of adult life, of sudden onset, characterized by local pain and by sensitiveness of the muscles themselves.

Strain of the back has as a rule a well-defined cause.

Like lumbago, its onset is sudden. The pain is usually localized at the point of injury and it is relieved by rest. In Pott's disease the pain is neuralgic, it is often worse at night, and the stiffness due to reflex muscular spasm is quite different from that caused by strain.

FIG. 4431.—Pott's Disease in Infancy, showing the Early Indication of Deformity.

Sciatica.—The pain of sciatica is most often unilateral; it is usually confined to the distributions of this nerve. The pain of Pott's disease, if it is referred to the legs, is usually bilateral. In sciatica movements of the limb often aggravate the pain, while motion of the spine is free or but slightly restricted. The reverse is true of Pott's disease. In persistent sciatica of long standing, lateral deviation and even rigidity of the lumbar spine are sometimes observed; but if the latter symptom is marked, the diagnosis may be regarded as open to question.

Sacro-iliac disease is far more likely to be mistaken for disease of the hip-joint than of the spine. The pain and sensitiveness are usually localized about the seat of disease, and the motions of the spine are but slightly restricted.

The attitude characteristic of Pott's disease of this region—viz., the hollow back, the prominent abdomen, combined with the waddling gait—may be simulated by bilateral congenital dislocation of the hip and by certain forms of nervous disease in which the muscles of the back are weak, as, for example, progressive muscular atrophy, or pseudohypertrophic muscular paralysis. In these affections the characteristic symptoms of bone disease are of course lacking.

Hip Disease.—When psoas contraction is present in lumbar Pott's disease it induces a limp, and not infrequently the patient complains of pain in the affected limb. These symptoms are usually mistaken for those of hip disease. The limp of Pott's disease is caused simply by flexion of the leg; when, therefore, in the physical examination the tension of the contracted ilio-psoas muscle is relieved by flexing the thigh still further, the other movements of the hip—flexion, rotation, and the like—may be shown to be free. In hip disease all motions are restrained in equal degree by muscular spasm.

Hip Disease in Infancy.—In infancy sympathetic spasm of the lumbar muscles is often present in hip disease, and a similar spasm of the muscles about the hip may accompany disease of the lower part of the spine. In doubtful cases of this character the application of a temporary support to the back and limbs, as, for example, a plaster spica bandage which will relieve the secondary spasm, is an aid in diagnosis.

Secondary Hip Disease.—An infected abscess in the neighborhood of the hip-joint may finally set up secondary disease of its structure, and in the presence of discharging sinuses that involve the tissues about the hip it is not always possible to decide whether or not the joint is actually diseased.

Pelvic Abscess.—As abscess is a common complication of Pott's disease it will be necessary to consider abscesses of other origin within the pelvis or in the neighborhood of the spine that may induce symptoms resembling somewhat those of Pott's disease. The most common abscesses other than those resulting from disease of bone are the perinephritic and appendicular. As a rule these are of sudden onset, and are attended by local pain and by constitutional symptoms. There is of course no deformity of the spine.

Chronic abscess in the pelvis, of other than spinal origin, may be the result of disease of the pelvic bones, or of the sacro-iliac articulations, or of the hip-joint. It may be caused by the breaking down of lymphatic glands, or it may have its origin in inflammation about the uterine appendages, and cases of so-called idiopathic inflammation and suppuration of the ilio-psoas muscle have been described. In childhood chronic abscesses in this locality are almost always tuberculous in character, and are caused by disease of bone, either of the spine or of the pelvis. Disease of the spine can be determined usually by the methods already indicated, but, if the abscess is of other origin, its exact cause can be decided in many instances only by an operative exploration.

Abscesses of this character, of slow and apparently painless formation, may finally cause a swelling in the inguinal region or about the saphenous opening, that in the adult is not infrequently mistaken for hernia. In practically all cases, however, the tumor of the abscess may be made out on palpation within the pelvis, while the swelling, although its contents may be in part forced into the abdominal cavity, feels very differently from that of an ordinary hernia, which may usually be completely reduced. In addition, some sign of the disease of the spine or pelvis, of which the abscess is a result, is almost always present.

Pott's Disease in Infancy.—Attention has been called to the great importance of carefully observing the movements and postures of the patient, and of noting the contour of the spine when the patient is in the erect attitude. In Pott's disease of infancy such observations are of course not possible. As a rule at this age the muscular spasm is more intense and its extent is greater. The child screams when it is moved or lifted. There is usually no difficulty in determining the presence of disease from the evidence of rigidity and pain, but, as has been stated, it is sometimes difficult to decide whether the lumbar spine or one of the hip-joints is involved. Slight

FIG. 4432.—Illustrating the Change from the Normal Contour, made Evident when the Patient Bends Forward.

irregularity of the spinous processes, indicating the position of the destructive process, is often evident at an early stage and early abscess is not unusual.

Pott's disease of infancy and early childhood is most often mistaken for *rachitic deformity*, or, rather, this deformity is often mistaken for that of Pott's disease.

The diagnosis from Pott's disease should be made without difficulty. The characteristic deformity of rachitis is a rounded projection of the middle and lower part of the spine. It is simply an exaggeration of the contour of the sitting posture which the rachitic child habitually assumes, a posture that would be painful if actual disease were present in this situation.

If the patient be placed in the prone posture the projection may be reduced in great part by raising the thighs while gentle pressure is exerted upon the kyphosis; and although the spine is somewhat rigid, and although such extension and pressure may be resisted by the patient, yet there is complete absence of the muscular spasm characteristic of Pott's disease.

Disease of the Middle Region.—As motion in the thoracic region of the spine is limited, the early symptoms of disease are far less marked than in the region below. On the other hand, a slight exaggeration of the normal dorsal kyphosis causes noticeable deformity. Thus it is that deformity may be the first symptom that attracts attention.

The effect of the disease upon the attitudes varies. If the disease involves the lower part of the thoracic segment, and if it be at all acute, they are similar to those of disease of the lumbar region, namely, erectness, the peculiar cautious intoeing step, and the disinclination to bend the body forward.

In disease of the upper dorsal region there is usually a slight forward inclination of the body while the head is tilted backward or inclines toward one side. A peculiar shrugging squareness and elevation of the shoulders is often noticed, due in great part to the lowering of the head and forward inclination of the neck resulting from the deformity. Another effect is pigeon-chest. As the deformity progresses the sternum is thrust forward and the antero-posterior diameter of the chest is increased at the expense of its height. This deformity of the chest may be the first symptom to attract the attention of the parents.

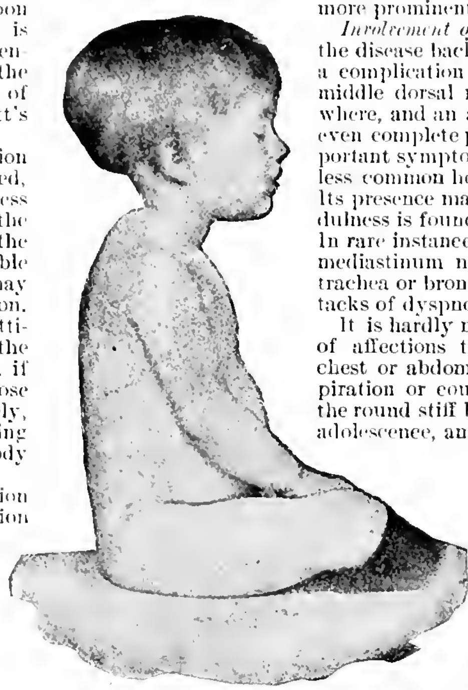

FIG. 4433.—Pott's Disease at the Cervico-dorsal Junction, showing the Effect of the Deformity in Thrusting the Neck Forward.

Of the early symptoms of dorsal disease pain and labored or "grunting" respiration are the most characteristic.

Pain referred to the abdomen and to the front and sides of the chest is usually an early and often a constant symptom. Thus, persistent "stomachache" in a child should always lead the physician to make an examination of the spine. A "spasm of pain" is sometimes excited by lateral compression of its chest, as when the child is lifted suddenly by the parent.

Of still greater importance is the labored respiration, which, indeed, is almost pathognomonic of Pott's disease. The "grunting" is caused by the interference with respiration, more particularly with the normal rhythmical movements of the ribs. The restraint is in part due to muscular spasm and in part to the voluntary efforts of the patient. The inspiration is quick and shallow, in great degree diaphragmatic, and expiration is accompanied by a sigh or grunt. This is apparently caused by a momentary closure of the larynx to resist the escape of air and thus sudden motion of the chest wall. Grunting respiration is of course an evidence of the more acute type of disease, but even in mild cases it is usually present when the patient is fatigued or during play. An irritating aimless cough is often a symptom of disease of the upper dorsal region, and spasmodic attacks resembling asthma are not uncommon.

When symptoms have existed for any length of time the characteristic angular kyphosis is usually apparent on physical examination, or at least the significant break in the contour of the spine when the patient is inclined forward.

In tracing the neuralgic pain to its origin, the sharp downward inclination of the ribs must be borne in mind: thus the cause of pain in the "stomach" must be looked for between the shoulder blades.

As in the lumbar region, slight lateral deviation of the spine is not uncommon, and it may be accompanied by a slight twist or rotation, so that the ribs on one side are more prominent.

Involvement of the cord from extension of the disease backward is far more commonly a complication of disease of the upper and middle dorsal region than of disease elsewhere, and an awkward stumbling gait or even complete paralysis may be the first important symptom of the disease. Abscess is less common here than in the lower region. Its presence may be suspected if an area of dulness is found by the side of the kyphosis. In rare instances an abscess in the posterior mediastinum may press directly upon the trachea or bronchi and cause spasmodic attacks of dyspnœa resembling asthma.

It is hardly necessary to mention the list of affections that may cause pain in the chest or abdomen, or induce a labored respiration or cough. As regards deformity the round stiff back, a postural deformity of adolescence, and the rachitic kyphosis may be excluded without much difficulty. Spondylitis deformans, the typhoid spine, and the like differ essentially in history and symptoms. Acute or chronic affections within the chest may cause pain and even deformity of the spine. Such disease, however, could hardly be mistaken for Pott's disease. The abscess of Pott's disease in this region, as has been mentioned, causes dulness or flatness on percussion of the chest, and within this area friction sounds and râles may be heard. If the diagnosis of Pott's disease had not been made, or if the presence of the abscess had not been determined by the previous physical examination, it might be mistaken, during an acute exacerbation of the disease or constitutional disturbance from other cause, for pleurisy or empyema, and at other times for phthisis. The tuberculous fluid may remain indefinitely in the posterior mediastinum, and the area of flatness may extend beyond the axillary line, yet it may give rise to no symptoms.

In all cases a careful examination of the chest should be made from time to time in order that the presence or absence of abscess may be recorded.

The Upper Region.—The upper region of the spine, which includes the cervical and two of the dorsal vertebræ, is a region of free movement. This movement is in part true joint motion; thus it is necessary to consider disease of this portion apart from that of the remainder of the upper section. Occipito-axoid disease is comparatively rare, and relatively more frequent in adult life than in childhood. It is especially dangerous because the displacement or fracture at this point may cause sudden death by pressure on the vital centres. In a typical case the symptoms are neuralgic pain radiating over the back and sides of the head, following the distribution of the auricular and occipital nerves. The head is usually inclined forward and rotated slightly to one or the other side of the median line. There is usually thickening of the tissues on the posterior and lateral aspects of the neck, and there is in most instances sensitiveness to deep pressure. As a rule motion in these joints is absolutely restricted, as is shown when one attempts to move the head up or down or from side to side.

In disease of this region if an abscess appears it usually presents itself on the posterior or lateral aspect of the neck, but in some instances it forces its way forward as a retro-pharyngeal abscess. In such cases the symptoms may be characteristic of obstruction, such as snoring, change in the quality of the voice, difficulty in swallowing, and sometimes spasmodic attacks of so-called croup.

When an abscess is present, and when the disease is at all acute, the reclining posture often increases the symptoms.

The symptoms of disease of the middle cervical region are similar to those of the upper dorsal section. There is usually a backward inclination of the head if deformity is present. In other instances the head may be turned to one or the other side, so-called false torticollis. Deformity at the upper extremity of the spine straightens the natural anterior curvature in the cervical region, and as a result there is compensatory flattening of the back; thus a short neck and a flat back are often the most prominent physical signs of disease of this region.

The distortion of the head symptomatic of Pott's disease is sometimes mistaken for torticollis. From chronic torticollis it may be easily distinguished, because in this distortion there is limitation of motion only in the direction opposed to the contraction and there are no accompanying symptoms. From so-called acute torticollis caused by enlarged or suppurating glands, or following irritation of the nose or pharynx, the diagnosis may be more difficult; but in this affection, if the head be inclined toward the contracted muscles, motion in other

FIG. 4434.—Atlo-axoid Disease, showing the Characteristic Attitude.

directions will be unrestricted, whereas in Pott's disease all movements are checked by muscular spasm. It may be stated also that the distortion of Pott's disease is often irregular, and there is no evident contraction of certain muscular groups, such as is usually present in simple torticollis.

Injury.—Injury of the upper segment of the spine may cause pain and stiffness and deformity, symptoms that could not be distinguished from those of Pott's disease but for the history of the case.

Weakness of the posterior muscles following diphtheria may cause a forward droop of the head. Spasm of the posterior muscles is sometimes seen incidental to meningitis and even as a less serious symptom in weakly children, but such deformities can hardly be mistaken for Pott's disease.

Abscess may cause symptoms of obstruction in the throat which might be mistaken for that due to adenoid growths or enlarged tonsils. It may be mentioned also that the seventh cervical vertebra often forms a noticeable projection at the base of the neck. In hysterical or hyperæsthetic individuals these symptoms are sometimes mistaken for those due to disease.

Forms of organic diseases of the spine other than tuberculous are described elsewhere.

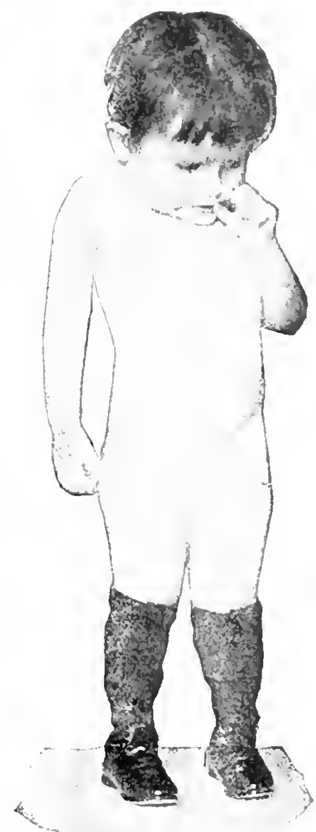

FIG. 4435.—Pott's Disease of the Upper Cervical Region, showing the Characteristic Deformity in an Untreated Case.

The diagnosis having been established, an accurate record of the case should be made. This should include the general condition of the patient, the character of the disease, whether acute or quiescent, and the presence or absence of complications. The position and character of the deformity should be recorded by means of a tracing of the entire length of the spine, such a tracing being made by means of a strip of lead or tin while the patient is lying extended in the prone position.

TREATMENT.—Pott's disease is the most important of the tuberculous affections of bone, and the importance of proper surroundings, nourishing food, open air, and sunlight can hardly be exaggerated.

Special orthopedic treatment is essentially mechanical; its object is to resist the natural tendency of the disease toward deformity.

Under normal conditions the weight of the head and of the thoracic and abdominal organs tends to bend the spine forward. If the support is weakened by the direct destruction of the weight bearing portion of the spine this tendency is greatly increased. It is evident, therefore, that the force of gravity is a very important factor in the production of deformity. Flexion of the spine compresses the vertebral bodies; extension of the spine relieves this pressure and transfers it in part to the articular processes.

The object of a brace or other support in the treatment of Pott's disease is to hold the spine in the extended position and to prevent motion at the seat of disease. The effectiveness of any splint depends upon the accuracy of its adjustment, and it is apparent that such adjustment is more difficult in certain regions of the spine than in others. For example, if the disease involves the lower thoracic region the splint is likely to be effective because its two extremities attached to the pelvis and to the shoulders are equally distant from the point to be supported; but if the upper thoracic region is affected, it is difficult to fix the spine because of the insufficient leverage of the supporting appliance. Even if the brace is accurately adjusted it cannot remove entirely the jar and strain incidental to the upright posture. It is evident, therefore, that complete rest can be assured only in the attitude of recumbency.

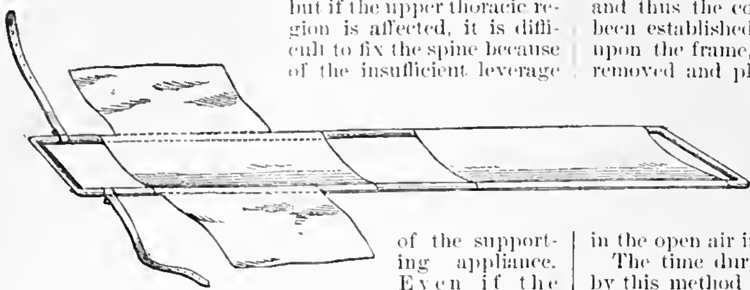

FIG. 4436.—The Bradford Frame.

Treatment by Horizontal Fixation.—A number of appliances to assure horizontal fixation are in use, but the most effective and convenient support is the Bradford frame or stretcher. This is a rectangular frame of ordinary gas pipe, a few inches longer and a little wider than the patient's body, covered with canvas or cotton cloth, except for an interval in the centre, as shown in the illustration (Fig. 4436.).

This appliance may be modified with advantage in the following particulars: it should be made slightly narrower than the patient's body, its width corresponding to the distance between the articulating surfaces of the shoulder-joints. The cover should be made of strong canvas in one piece so that it may be drawn tight by means of straps and corset lacings (Fig. 4437.). The centre should be covered by rubber cloth. Upon the canvas cover opposite the seat of disease should be sewed two pads of felt about six inches long, one inch wide, and half an inch thick. These should be parallel to one another and about one inch apart. They protect the spinous processes from pressure, and aid in fixing the spine. The patient, in most instances a young child, wearing simply a shirt and diapers, is then placed upon the frame, and is fixed to it by means of a front piece of canvas, as shown in the illustration. If the disease is of the upper region, the head should be fixed by an appliance similar to the ordinary jury-mast; if it is in the lower region the movement of the limbs should be restrained by means of a swath or by traction straps. When the frame has been adjusted the child's clothing is put on, having been made sufficiently large to include it and the frame. This illustrates the advantage of making the appliance as narrow as possible. When the patient has become accustomed to the restraint the frame is gradually bent backward until at the end of a few weeks the spine is forced, if possible, into an attitude of extreme overextension. (Fig. 4438.)

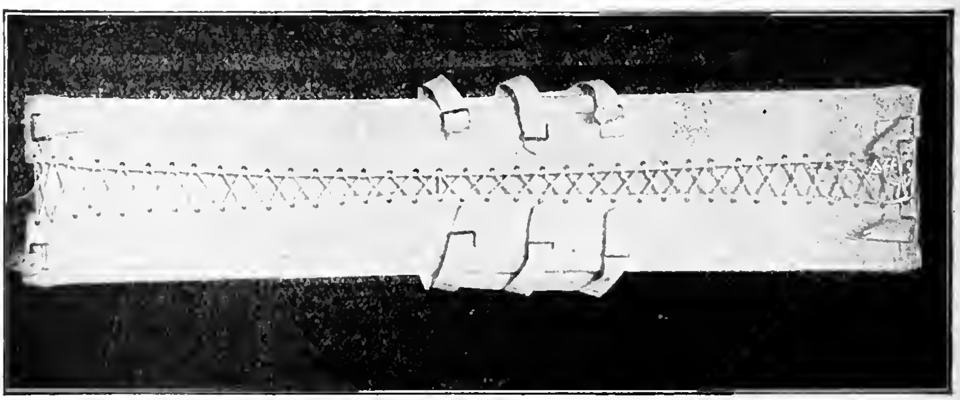

FIG. 4437. The Modified Stretcher or Bradford Frame, showing the Covering.

In favorable cases treated in this manner the deformity may be entirely obliterated, and as it is evident that the diseased vertebral bodies have been separated from one another, friction and pressure must have been removed and thus the conditions most favorable for repair have been established. The patient is kept constantly fixed upon the frame, except that once a day he is carefully removed and placed face downward on a pillow. The back is then rubbed with alcohol and powdered, the frame cover is cleansed, and the child is then replaced upon it. As has been stated, the child wears diapers, and a dust-pan serves as a convenient form of bedpan. As much of the time as possible is passed in the open air in the ordinary baby carriage.

The time during which the patient should be treated by this method varies with the severity of the disease. As a rule it is from six to eighteen months. The indications for its discontinuance are the subsidence of the symptoms and the behavior of the patient. A child suffering from active disease almost instantly recognizes the benefit of treatment and dislikes to be removed from the frame; but when repair is advanced he becomes impatient at the restraint, and when he begins to crawl about with the frame on his back and to attempt to stand, it is evident that the necessity for this mode of treatment is passed.

Although there is a strong prejudice against this form of treatment, I have never noticed ill effects from it, even when it has been long continued. The patient usually gains in weight and often grows rapidly, more rapidly in fact than those who are allowed to go about.

It is apparent that this form of recumbent treatment, although by far the most efficacious, is limited practically, as a routine practice at least, to early childhood, that is, to patients of four years or less, who can be carried about in arms. As a treatment for special cases, or to meet special indications, it has, however, no limit of age. For older patients the cover should be made in two parts, as in the original Bradford frame, to allow for the use of the bedpan.

Horizontal fixation must be supplemented of course by a support for the weakened spine when the erect posture is again assumed, and ambulatory treatment by such means is in the majority of cases the only one that is employed. These supports are either in the form of metallic braces applied along the spine or as circular supports, of which the plaster jacket is the common form. The object of every form of appliance is to remove as far as possible the weight from the weakened vertebral bodies by holding the trunk in the extended position, and to prevent motion at the seat of disease.

The Back Brace.—The most efficient spinal brace consists essentially of two steel bars that are applied on either side of the spinous processes from the top to the bottom of the spine (Fig. 4439.). The attachment at the lower end is made by means of a pelvic band of sheet steel (gauge 18) from one and a half to two inches in width, long enough to reach from one iliac spine to the other. It is placed as low as possible on the pelvis—in other words, just above the upper extremities of the trochanters. To this the uprights are firmly attached at an interval of from one and a quarter to one and three-quarter inches from one another, so that the spinous processes may pass between them while pressure is made on the lateral masses of the vertebræ. The uprights are made of varying strength according to the age of the patient, usually about one-half an inch in width (of gauges 8 to 12), and of such quality of steel that although unyielding to the strain of use it may be readily bent by wrenches and thus accurately adjusted to the back. The uprights reach to the root of the neck, or to about the level of the second dorsal vertebra. From this point two short arms of metal project forward and outward on either side of the neck, reaching to about the middle of the clavicles. To these are attached padded shoulder straps, which pass under the arms to a crossbar on the back brace; thus downward pressure on the shoulders is avoided and increased leverage is assured.

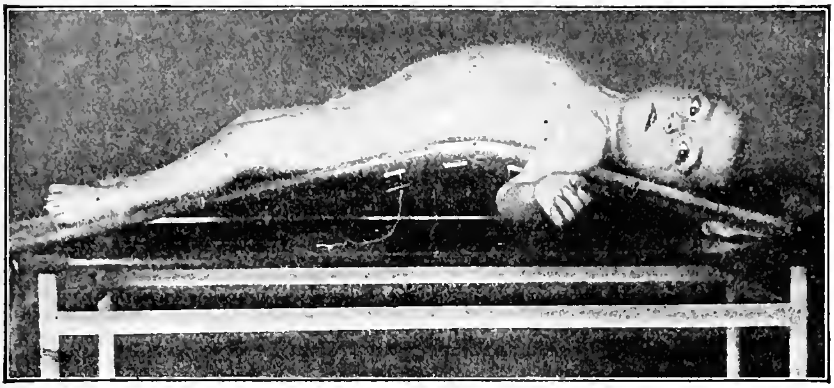

FIG. 4438.—The Stretcher Frame, showing the Attitude of Overextension.

FIG. 4439.—Whitman's Shoulder Brace; side view.

Opposite the point of disease two strips of this steel, about three-quarters of an inch in length, are fixed. These are slightly wider than the uprights, and are perforated for the attachment of the pressure pads, made of layers of Canton flannel or felt, or of unyielding material, such as leather or hard rubber if this is preferred.

The pads should project from a quarter to a half inch in front of the uprights in order that firm and constant pressure, to the extent that the skin will tolerate, may be made at the seat of disease.

In measuring for this brace the patient is placed in the prone posture and a tracing of the outline of the back, beside the spinous processes, is made by means of the lead tape. This outline may be cut in card-board and fitted to the back; in fact, if the mechanic is unfamiliar with the work, each part of the brace, uprights, pelvic band, etc., may be cut in card-board and attached to one another to serve as a model. Before the brace is finished it should be applied to the back, and should be carefully adjusted by means of wrenches. The pelvic band is then padded and the parts that come in direct contact with the skin are usually covered with leather, or, in the treatment of young children, with rubber plaster and Canton flannel, to prevent rusting.

If the brace is applied before the stage of deformity, it should follow the exact shape of the normal spine; but if deformity is already present, particularly in disease of the thoracic region, it should be made somewhat straighter than the compensatory curves above and below the projection, in order to permit a gradual straightening of the compensatory lordosis in the lumbar region, and for increased leverage above the deformity. As has been stated, a certain amount of recession of deformity can be obtained by rest in the horizontal position; and if practicable this improved contour should be attained before the brace is applied. The apparatus is held in place by an "apron," which covers the chest and abdomen, and to which straps are attached. Ordinarily this is made of strong linen or cotton cloth, but a canvas front, shaped accurately to the body and strengthened with whalebone as is a corset, is a much more comfortable and efficient support (Fig 4440.). In applying the brace with the patient in the recumbent posture the pelvic band is first attached to the apron, then the straps in order from below upward, and finally the shoulder straps. Each strap is then tightened until the brace is firmly fixed in proper position. When a brace is properly applied and properly fitted, it holds its place by friction; but in certain cases when the disease is low in the back, it is sometimes of advantage to apply perineal straps to hold the pelvic band firmly in its place.

FIG. 4440.—Whitman's Brace, with Chin-piece Applied.

At first the brace is removed once a day in order to wash and powder the back, the same care being observed in moving the child as in the treatment by the frame; but when the back has become accustomed to the pressure, the brace should be removed only at infrequent intervals, and thus, if need be, only under the supervision of the surgeon.

This description indicates the essential qualities of the back brace. It has been modified in various ways. For example, Dr. Taylor, its inventor, finally discarded the straight pelvic band in favor of one of a **U** shape, as shown in the illustration (Fig. 4441). This makes the brace somewhat lighter and relieves the sacrum from the pressure of the pelvic band, but it does not add to its effectiveness. The efficiency may be increased, however, by improving the attachment at its upper extremity. Taylor has accomplished this by placing two triangular pads against the chest. If, however, the disease is of the upper and middle segment of the thoracic region, more efficient support is of advantage; for in such cases the upper part of the chest is flattened, the inclination of the ribs is increased, and the shoulders incline forward, carrying with them the scapulæ. Thus the weight and the strain of the motion and use of the arms tend to increase the deformity.

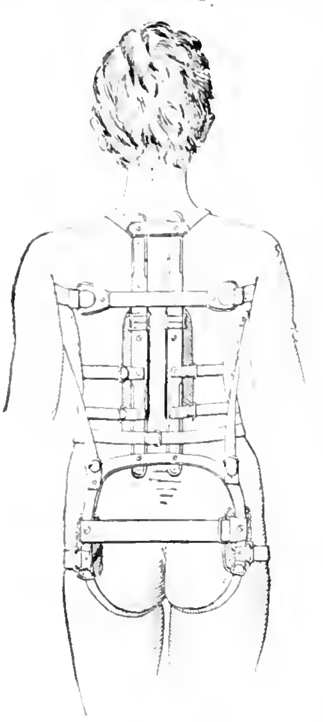

FIG. 4441. The Taylor Back Brace.

In health direct forward or reaching movements of the arms are always accompanied by an increase in the posterior curvature of the dorsal spine. On the other hand, if the shoulders are drawn backward and held in this attitude, the curvature of the spine is lessened and the chest is elevated and expanded.

In the treatment of disease of the upper dorsal region it should be the aim, in the application of a brace, to follow this indication and to apply pressure directly upon the extremity of the shoulders, to assure the greatest possible fixation of the spine, and to restrain the movements of the arms that tend to increase the deformity.

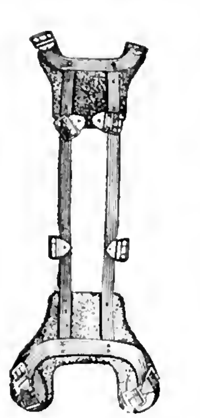

FIG. 4442. Modified Taylor Spinal Brace.

The accompanying diagrams show how such support should be applied (Figs. 4443 and 4444). Two saucer-shaped plates of hard rubber or padded metal cover the heads of the humeri, and are joined by a rigid bar of steel which passes across, but does not touch, the chest. On the back brace are placed two triangular pads of similar construction, which cover and press upon the scapulæ. These pads are, however, not essential, and are often omitted. The back brace is applied, the shoulders are then drawn backward, and the shoulder cups are firmly attached by straps to the neck bars of the brace above and below by axillary bands in the usual manner. By this means the thorax is elevated and the spine more effectively fixed, while direct movement of the arms forward is made impossible. It would seem that such restraint would be irksome to the patient, but in an extended use of the apparatus I have never heard this complained of. In many instances, even when the disease is as low as the tenth dorsal vertebra, this form of brace may be used with advantage, but it is especially indicated when the disease is in the neighborhood of the seventh dorsal vertebra. In connection with the shoulder brace it is usually advisable to apply a support beneath the chin to prevent the forward inclination of the neck and to tilt the head somewhat backward.

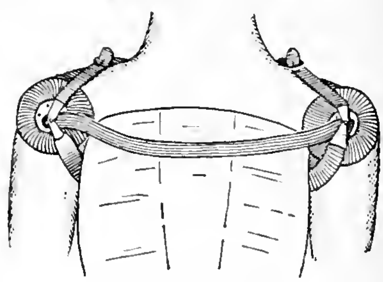

FIG. 4443.—Whitman's Brace; front view.

A very simple and inoffensive support of this character is a loop of steel surrounding the neck and attached by screws to a back bar on the brace (Fig. 4445). If a more efficient brace is required, as when the disease is of the upper dorsal or cervical regions, the Taylor head support should be used (Fig. 4446). This is an oval ring of steel, which may be clasped about the neck by means of a lateral hinge. On the front a cup of hard rubber supports the chin, and behind the ring fits upon an upright pivot, that may be raised or lowered upon a crossbar on the upper part of the brace. Free lateral motion is allowed, or it may be checked by means of a screw.

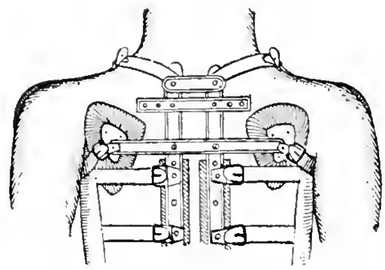

FIG. 4444.—Whitman's Brace; rear view.

If absolute fixation of the head is indicated, as in disease at or near the occipito-axoid region, two steel uprights are attached to the back of the ring, and are bent to fit the posterior and lateral aspect of the head closely. If necessary, a band of webbing is passed from one upright to the other and about the forehead.

In applying the support the chin should always be slightly tilted upward in order to throw the weight of the head backward.

The adjustment of the head support is made easier if the pivot is attached to the upright by means of a ball-and-socket joint (Shaffer) that may be regulated by a screw and key. This arrangement is of service when the head is distorted, but it is by no means necessary.

When the Taylor head support and similar appliances are used, the greater part of the pressure is sustained by the chin, which may after a time undergo an unsightly recession. It may be of advantage therefore in certain cases, particularly when restraint of the motion of the neck is desirable, to transfer this pressure to the forehead by means of a strap attached behind to light bars of metal shaped to the occiput and attached to the upper extremity of the brace (Figs. 4448 and 4449).

FIG. 4445.—Chin-piece to Whitman's Brace.

A jury-mast may be used to support the head also. Its adjustment will be described in connection with the plaster jacket, with which it is usually associated.

The Plaster Jacket.—It was at one time claimed that a plaster jacket applied while the body was partially suspended would actually relieve the weakened area of superincumbent weight by holding the diseased surfaces apart; but it is now generally conceded that the jacket supports the spine, as does the brace, by holding it in the erect or extended position. One is a circular and the other a posterior splint. There is this difference, however: the brace fits the spine accurately and holds its place by pressure and friction. The jacket is held in place by the support of the projecting pelvic bones. It lacks the accuracy of adjustment of the brace at the seat of disease; but, on the other hand, it provides a solid support on the front and sides of the body that may be even more effective.

FIG. 4446.—Whitman's Anterior Shoulder Brace Applied with the Taylor Brace and Head Support.

Each appliance has advantages and disadvantages that become apparent in the treatment of certain phases of the disease or conditions of the patient.

The plaster bandage is a simple support whose efficiency depends upon the accuracy of its adjustment to the irregularities of the body, and upon the leverage that it exerts above and below the point of disease. It should be applied while the body is held in the best possible position. Its inner surface should be smooth, and the bony prominences that are susceptible to friction and pressure should be protected. A seamless shirt should be worn. These are made in several sizes and are sold by the yard at a low price. The shirt should fit the body closely and should be long enough to reach to the knees. The patient is then placed upon a stool and the halter of the suspension apparatus is carefully adjusted. The arms are extended over the head and the hands clasp the straps or rings; thus the chest is expanded to its full limit. Sufficient tension is made upon the rope partially to suspend the body and to draw the spine into the best possible attitude. In most instances the heels should be slightly lifted from the stool.

FIG. 4447.—Whitman's Shoulder Support with the Taylor Brace.

Dr. Sayre, to whom we are indebted for the exposition of this valuable means of treatment, insists that the sensations of the patient should be the guide, and that traction should be made only to the point of comfort. This is a valuable indication in the treatment of the adult, but it is not often of service in childhood.

Before the plaster bandage is applied pieces of piano felting or Canton flannel of sufficient size should be placed about the anterior pelvic spines and over the upper part of the sternum. A thin strip of the same material may also be used to cover the spinous processes. Finally, long strips of saddler's felt, or other material of sufficient thickness, are applied on either side of the prominent spines to protect them from friction, and to provide greater pressure and fixation at the seat of disease. The "dinner pad" is now very rarely used, except in the treatment of adults and in certain cases of deformity in which the abdomen is retracted. In childhood the abdomen is usually prominent, and as the jacket expands somewhat no extra space is required. The pad, which is supposed to represent the space required after a full meal,

FIG. 4448.—An Appliance for fixing the Head, used with the Plaster Jacket.

is made by folding a napkin in the shape of a sandwich. To this a bandage is attached, and is placed beneath the shirt just below the ensiform cartilage. When the jacket is hard it is drawn out. Another long bandage is placed beneath the shirt, to remain permanently for the purpose of cleaning the skin beneath the jacket. The bandages should be freshly prepared of dental plaster, which should be rubbed into strips of crinoline from three to five inches in width and about six yards in length. From three to six of these are required according to the size of the child. As ordinarily applied by means of the swing the surgeon sits behind the patient, grasping the child's legs between his knees to prevent swaying of the body; and during the application of the bandages the layers of plaster should be constantly rubbed in order that the support should fit the body accurately. At the same time gentle pressure may be exerted with the aim of straightening or overextending the spine. It is well to make the first turn about the waist and use the first bandage about the pelvis, as this is the base of support. The bandages should also be applied with especial care across the upper portion of the chest, as this is the most important point for counter-pressure. When the jacket is nearly firm it should be trimmed, if practicable, while the patient is in the swing. As a rule, the front of the jacket

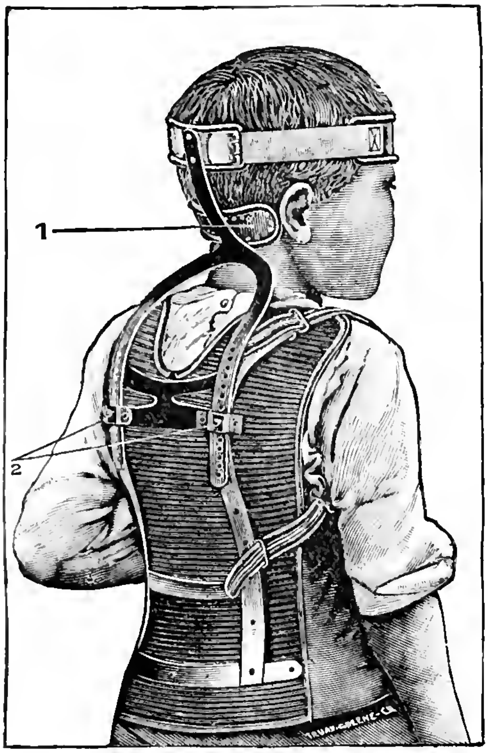

FIG. 4449.—Blanchard's Brace.

should extend from the top of the sternum to the pubes; behind, from the spines of the scapulæ to the gluteal fold. Laterally, it should be cut away sufficiently to prevent chafing of the arms, and below, too, in order to allow flexion of the thighs in the sitting posture. When properly applied, the jacket need not exceed a thickness of from one-eighth to one-quarter of an inch. The shirt is then drawn up over the jacket and sewed to the upper border, and the two ends of the bandage or skin rubber are tied together.

In the treatment of children by this means a protective bib should be worn to prevent crumbs from falling under the jacket, and at morning and night the skin should be vigorously rubbed by means of the bandage. In many instances the anterior shoulder brace, already described, may be used with advantage. This may be attached to buckles incorporated in the back of the jacket.

If the disease is of the upper or middle region of the spine a head support is required (Fig. 4452). For this purpose a jury-mast is most often employed. This should be of tempered steel, and its base should be incorporated firmly in the jacket below the seat of disease. When it is properly applied the head should be tilted and drawn somewhat backward with so much tension as can be tolerated.

In place of the jury-mast a fixed support may be used, as shown in (Fig. 4448). Fixed supports of this character have an advantage over the jury-mast in the matter of security, for although the latter appliance is effective when properly adjusted, it is of no value when the straps are allowed to hang loosely about the head, as is the case in so many instances.

The Application of the Jacket in the Recumbent Posture.—For young children who have been treated on the frame a very satisfactory method is the following: The patient is suspended face downward by two assistants, one holding the arms and the other the thighs. Thus a certain amount of traction is exerted while the trunk is in the overextended position. The jacket is applied, and before it has hardened the patient is replaced upon the frame, and the spine becomes fixed in the habitual attitude. The jacket may be applied in the supine posture by means of the appliance devised by Goldthwait. The body is supported at the seat of disease by means of an upright, on which are placed two pads like those used in the Taylor back brace. The two extremities of the spine are then allowed to sink downward with the aim of extending the spine at the point of disease. The jacket is then applied about the central support, and when it is firm the patient is lifted from it, the two adjustable pads remaining within the jacket (Fig. 4453).

As a rule a jacket may be worn for three months, although in hospital practice six months is not unusual.

In the stage of recovery the jacket may be replaced by a corset. This is constructed as follows: A jacket applied in the manner described is cut through the centre and removed from the body. It is then thoroughly dried and trimmed, and strips of leather with hooks having been sewed in front, it may be laced like an ordinary corset. The corset should always be removed and reapplied with the patient in the suspended or recumbent posture. It should not be used during the active stage of disease.

In contrasting the two ambulatory supports that are in common use, the jacket and the metallic brace, it may be stated that the jacket has the great advantage in that the treatment is in the hands of the surgeon. It is inferior to the brace when the disease is in the lower lumbar region. The brace is to be preferred also when the disease is in the upper region, as in such a case the jacket serves only as a base for the head appliance.

FIG. 4450.—A Plaster Jacket Applied to Support the Abdomen, showing also the Method of Fastening the Shirt about the Neck. (From Whitman's "Orthopedic Surgery.")

In certain instances when the disease is in this situation, the jacket is carried over the shoulders and is made to include the head. This is an effective treatment, but rather cumbersome.

If the disease is seated in the lower region of the spine, and if it is accompanied by contractions of the thighs, the limbs may be encased by means of the spica jacket. As a rule, however, cases of this character are best treated by recumbency.

In certain instances the Thomas collar may be used. This is of especial service in atlo-axoid disease, where it may be used with or without the jury-mast. The shape is shown in Figs. 4454, 4455, 4456 and 4457). It is made of a piece of thin sheet metal, wide enough to reach from the sternum to the chin and from the back of the neck to the base of the occiput. The edges are turned out and the whole properly covered with pieces of felt and fitted. One may improvise a support of this character by making a thick muff-like appliance of absorbent cotton, which may be stiffened by layers of adhesive plaster on the exterior. The original form of collar is shown in the illustration.

Prognosis and Treatment as Influenced by the Situation of the Disease. The Lower Region.—The prognosis as regards deformity is favorable. The part may be easily supported. The cases are often seen before the deformity is extreme; and, as a rule, one may predict recovery without noticeable distortion. In most cases the trunk is somewhat shortened and a peculiar erect attitude persists. The most troublesome complications of disease in this region are psoas contraction and the abscess with which it is often combined. Slight psoas contraction usually disappears after the application of effective support. If it persists it is well to provide the patient with crutches. If it is a symptom of progressive disease and is accompanied by pain, the patient should be placed in bed, where, if necessary, the deformity may be reduced by traction. In confirmed cases in which the distortion has become fixed by secondary contraction of the muscles and fascia, operative treatment is occasionally required to overcome the deformity. In this region of the spine the plaster jacket or the spinal brace may be used, the former means being perhaps preferable. The most troublesome complication is abscess, which is present in about fifty per cent. of the cases.

FIG. 4451.—The Plaster Jacket from Behind. (From Whitman's "Orthopedic Surgery.")

Disease of the Middle and Upper Dorsal Region. — Disease of this region of the spine is not often acute in its onset, and in most instances deformity is advanced before treatment is begun. It is the region most unfavorable for treatment from the standpoint of prevention of deformity, for the reasons that have been stated.

Whenever possible the patient should be treated by recumbency in the overextended position until the progress of the disease has been checked. Support must be employed for many years because there is a tendency toward increase of the deformity even after the cure of the disease. The Taylor brace assures better fixation than does the jacket. In most instances the anterior shoulder brace should be employed for better support, and to prevent the forward movement of the arms; and whenever the disease is above the eighth dorsal vertebra a head support should be applied. In this region of the spine paralysis is the most important complication. This occurs in about ten per cent. of the cases.

Disease of the Cervical Region.—In disease of the cervical region the prognosis is good, the most noticeable

FIG. 4452.—The Anterior Shoulder Brace Applied with the Plaster Jacket and Jury-Mast.

deformity being the shortened neck and the forward thrust of the head.

Disease of the occipito-axoid region is uncommon. The tendency is toward fixation of the head in the attitude of flexion. This may be prevented by the use of apparatus. The jury-mast when properly applied is a thoroughly efficient support, but fixation of the head by means of the Taylor support or posterior splint insures better control of the patient when he is not under observation.

The Complications of Pott's Disease. Abscess.—It may be assumed that a limited collection of tuberculous fluid accompanies practically every case of Pott's disease; but unless it can be demonstrated by palpation or unless it

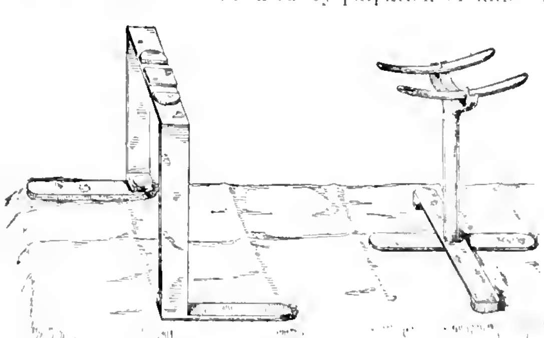

FIG. 4453.—The Goldthwait Frame as used with the Short Uprights in applying the Plaster Jacket.

appears upon the surface of the body it is not as a rule detected. Abscess as a complication in this sense is present in about twenty-five per cent. of the cases. It is far less common in the upper than in the lower region of the spine. This is accounted for in part by the fact that abscesses find their way downward, and in part because the large size of the vertebral bodies in the lumbar region offers better opportunity for their formation.

An abscess may appear without noticeable symptoms, but in many instances it is preceded by pain or discomfort, which indicates apparently tension at the seat of disease.

Abscesses are not as a rule accompanied by increase of bodily temperature, but when they are of large size and are approaching the surface, and especially when the skin covering them is reddened, there is usually a rise in temperature that implies apparently secondary infection of a mild type.

The Course of Abscesses in the Different Regions of the Spine.—Abscess accompanying disease of the occipito-

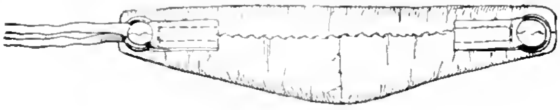

FIG. 4454. The Thomas Collar.

axoid region may force its way forward and appear in the throat as retropharyngeal abscess. More often it finds its way backward, distends the suboccipital triangle, and then passes forward to the region of the mastoid process. Abscesses from the middle cervical region pass outward and appear usually in the interval between the trapezius and the sterno-mastoid muscles.

In the thoracic region the abscess in the posterior mediastinum usually passes outward to perforate the intercostal muscles and appear on the posterior or lateral aspect of the chest. Or it may pass downward through the openings in the diaphragm and become an iliac abscess. Abscesses that originate in the lumbar region, or that have come from above, may follow various paths. Some perforate the sheath of the quadratus lumborum muscle and become a lumbar abscess, distending the skin between the twelfth rib and the crest of the ilium. Others pass downward on the surface of the iliac fascia and form a tumor at the outer extremity of Poupart's ligament or escape into the thigh. Psoas abscess burrows in the sheath of the psoas muscle and appears on the inner aspect of the thigh. Occasionally the fluid may escape from the greater sacro-sciatic foramen and appear as a gluteal abscess. In rare instances abscesses may take other courses. They may find their way into the spinal canal or break into the lung or into the intestines.

In most instances abscesses cause no direct symptoms, but occasionally from their size or situation they may

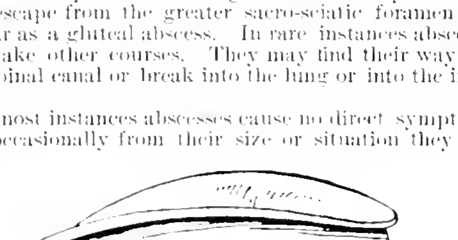

FIG. 4455. The Thomas Collar.

cause dangerous complications. The retropharyngeal abscess may interfere with breathing or swallowing. An abscess in the posterior mediastinum may press upon the trachea and cause attacks of inspiratory dyspnœa resembling asthma. Psoas contraction, which so often accompanies lumbar abscess, has been described already.

Treatment of Abscesses.—Abscesses that cause direct symptoms may require immediate treatment. The retropharyngeal abscess in case of emergency may be opened by direct incision in the throat. As a rule, however, a lateral opening in front of or behind the sterno-mastoid muscle is preferable. Obstruction due to mediastinal abscess is uncommon, and in such cases the abscess should be evacuated. An incision is made at the point of deformity over the articulation between the transverse process and rib. A portion of the latter is removed and

FIG. 4456.—The Thomas Collar Applied.

the abscess is exposed, lying as a rule directly in front of the spine. Care should be taken to follow the spine as closely as possible in order not to wound the pleura.

All infected abscesses should be opened and drained, but quiescent abscesses that cause no discomfort need not be disturbed, as a collection of tuberculous fluid is simply an incident of the original disease of the bone.

If an abscess is of large size, as, for example, when it distends the lumbar region or iliac fossa, the fluid may be evacuated by simple incision. The contents having been removed, the cavity is thoroughly flushed with hot salt solution in order to remove the shreds of necrotic tissue, and the wound may be then closed by layers of sutures. Drainage should be employed if the abscess is infected, or if the surroundings are such that subsequent infection may be avoided. It must be borne in mind that the danger of a tuberculous abscess is an indirect one, and this danger is from secondary infection, which does not often occur until a communication with the exterior has been established either by operation or by spontaneous evacuation. It is on this account that one hesitates to open abscesses when their source cannot be removed.

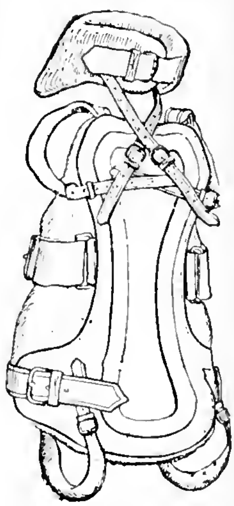

FIG. 4457. The Thomas Spinal Cuirass, with Collar.

Aspiration.—Aspiration serves a useful purpose in removing the thinner fluid and thus preventing the extension of the abscess. The injection of iodoform emulsion is sometimes employed after aspiration, although it is less in favor than in past time. The action of the iodoform is that of a local irritant, and it may be supposed to lessen the infectious quality of the tuberculous fluid. The ordinary form is a ten-per-cent. emulsion of iodoform in sterilized oil. A quantity varying from 4 to 30 gm., according to the size of the abscess, is injected at intervals of from two to four weeks.

In many instances abscesses disappear spontaneously by absorption, and after natural evacuation there is apparently no more danger from infection than after operative intervention, if cleanliness is assured.

It is apparent that the treatment of abscesses must be governed by the conditions in the individual case.

PARALYSIS.—The tuberculous process in the vertebral bodies may find its way backward into the epidural space, press upon the spinal cord, and thus cause paresis or paralysis of the parts below. In most instances the pressure is due to the inflammatory thickening of the coverings of the cord. Thus, in addition to direct pressure, there is often an interference with the blood supply and with the lymphatic circulation. As a result there are, after a time, an increase of the interstitial connective tissue and atrophy of the nervous elements, which may go on to partial or complete sclerosis. As a rule, however, but little permanent damage results, even from long-continued pressure and paralysis.

Occasionally paralysis is due to the pressure of an abscess; and when it is of sudden onset it may be caused by a breaking down of a vertebral body, which allows pressure of the thickened tissues upon the cord. In cases of this character the paralysis is at once relieved by straightening the spine.

The calibre of the spinal canal is not lessened by the characteristic angular deformity; in fact, paralysis more often accompanies slight than extreme distortion.

Paralysis not infrequently complicates disease in the upper and middle dorsal regions of the spine, occurring in about ten per cent. of the cases. It is an unusual complication of disease of other regions of the spine.

Symptoms.—The early symptoms, as noted by the patient or his friends, are weakness and an awkward shambling gait. The symptoms usually increase rapidly until paralysis of motion is complete. The extent of paralysis depends upon the situation of the pressure; thus the paralysis is most evident in the legs. There is an increase of the reflexes; and although when the patient is quiet the limbs appear limp, when he is moved, or when the reflexes are stimulated, the peculiar spastic rigidity appears. As a rule, the rigidity increases with the duration of the disease, and in cases of long-standing flexion contraction becomes permanent. This indicates irretrievable damage to the cord. Sensation is retained in the ordinary cases, but in those of the more severe type it may be impaired or lost.

When the paralysis is incomplete, control of the bladder is retained; but usually there is incontinence. As the bladder fills, the reflex centre is excited and it empties itself. The control of the sphincter ani is less noticeably impaired.

If the pressure on the cord is in the cervical region the arms are involved in the paralysis. If it is in the lower portion of the spine the symptoms are weakness and impaired sensation. The reflexes are not exaggerated.

Time of Onset.—Occasionally paralysis may precede deformity, but as a rule it is a late symptom, appearing more often from one to two years after the beginning of the disease.

Duration.—In exceptional cases in which the paralysis is caused by temporary pressure or disturbance of the circulation, it may be relieved at once by straightening and supporting the spinal column. If, however, the paralysis is complete, as it is in most instances, it persists usually for at least six months, and not infrequently for a year or longer, recovery being dependent upon the organization of the tuberculous granulations or disappearance of the abscess that causes pressure.

Prognosis.—In properly treated cases the prognosis is very favorable. In about seventy-five per cent. of the cases practically complete recovery occurs; absolute and permanent paralysis is unusual. Recurrence of the paralysis after an apparent cure is not uncommon, being dependent of course upon the persistence of the local disease.

Treatment.—The treatment of the paralysis is in great degree included in the treatment of the disease of which it is a symptom. If possible, rest on the stretcher frame in the position of overextension should be employed. If the disease is in the upper region of the spine traction upon the head is of value. In many instances the additional fixation secured by a plaster jacket should be used also.

If there is persistent contraction of the lower limbs restraint and traction should be applied. Counter irritation, such as the local application of the actual cautery, is thought by some to exert a favorable influence upon the disease. Iodide of potassium in large doses may aid in bringing about the absorption of the granulation tissue.

The first indication of improvement is a lessening of the muscular rigidity; then there is a gradual return of voluntary motion.

The exaggerated reflexes persist long after the disappearance of the paralysis.

Operative Treatment.—Operative treatment may be required in exceptional cases. If the presence of an abscess in the posterior mediastinum can be demonstrated it is well to evacuate it before opening the spinal canal, because the pressure may be due to the collection of fluid. If after persistent mechanical treatment there is no improvement in the paralysis, the operation of laminectomy may be undertaken. Eighteen months has been suggested as the limit of time which should have tested the efficacy of mechanical treatment.

The usual method of operating is as follows. A long incision is made parallel to and close by the side of the spinous processes. The muscles are drawn to one side, the spinous processes of several of the vertebræ at the seat of disease are cut through at their bases, and with the attached tissues are drawn to the opposite side. The laminæ are then removed with cutting forceps, exposing the dura mater. The thickened tuberculous tissue is usually found by the sides and in front of the cord. As much of this should be removed as is practicable. The wound is then closed and the spine is supported by a plaster jacket or other appliance.

Forcible Correction of the Deformity of Pott's Disease. Calot's Operation.—In 1896 the ancient operation of forcible straightening of the deformity of Pott's disease was revived by Calot of Berck-sur-Mer, and for several years the proceeding was in favor; but it has now been practically abandoned, at least as a measure of routine. Experience proved that in the milder cases the deformity might be overcome by rest upon the back, or even by the application of corrective jackets, while in the cases in which the destruction of bone was extensive, the recurrence of deformity after correction was practically inevitable. At the present time the operation is restricted to cases in which the deformity is of recent onset, and in which, it may be assumed, the disease is limited in extent. Forcible straightening of the spine separates the vertebral bodies at the seat of disease, and thus places the spine in a position favorable for repair; but, unfortunately, there appears to be but slight power in the spine to throw out new tissue to fill the interval that is made. If, then, forcible correction of the spine is employed, one should be prepared to fix the spine in the over-corrected position for at least a year. This necessitates, as a rule, rest in the horizontal position.

As the operation is ordinarily performed the patient, having been prepared as for the application of a plaster jacket, is anæsthetized, and is then suspended face downward, manual traction being exerted upon the arms and legs, and also upon the head. The deformity is then overcome by the application of gradual direct pressure upon the kyphosis. Thick pads are placed on either side of the spine. A large so-called "dinner pad" is inserted under the shirt and a strong jacket is applied. The patient is then placed in bed upon a pillow, or else upon the stretcher frame.

Great care should be taken to prevent pressure upon sensitive points, and as a rule, if much pressure has been applied, the plaster should be cut away to allow inspection at the seat of disease. As has been stated, cases in which the disease is of long standing should not be subjected to this operation, nor should cases complicated by abscess. On the other hand, paralysis is rather an indication for the operation than against it. In suitable cases the procedure is practically without danger.

Duration of the Treatment of Pott's Disease.—The duration of treatment must depend upon the extent and the severity of the disease. It may be divided into two stages, one in which the disease is active, when absolute fixation is indicated, and a stage of recovery in which supervision is required. Tuberculosis of the spine is slow in progress and recovery is insecure. The course of the disease is shortest in the cervical region, but even here brace treatment will be required for at least two years. In the lumbar region twice this time may be assigned to this period, and in the upper and middle dorsal regions, where the deformity may increase long after the cure of the disease, support may be required indefinitely.

Indications of Recovery.—As pain is almost always relieved by efficient treatment, its absence is no indication of cure. Muscular spasm usually persists as long as the disease is active; it is therefore a valuable indication in prognosis. The appearance of the kyphosis has some significance. In the early stage of disease the area of the destructive process is not defined; but when consolidation has taken place, its extent is shown by the rigid vertebræ that stand out from the remainder of the spine separated from it by a well marked depression, deeper below than above. In all cases removal of support must be gradual and its effect must be watched. When the disease is cured massage of the muscles, breathing exercises, and mild gymnastics may be employed with advantage. It may be noted that abscess or even paralysis may appear many years after the apparent cure of disease.

If recovery from Pott's disease has been complete, and if the deformity is slight, the individual may be to all intents normal; but if the deformity is great, his condition is abnormal, and he is unfitted for ordinary occupations. Such individuals usually suffer from neuralgic pain about the weakened spine, and in most instances some form of light support must be worn.

SPIROMETER. See *Respiration.*

SPLEEN.—In the following description of the spleen the physiological is blended with the anatomical, for in the present state of our knowledge of the subject it is practically impossible to separate them. Throughout the article the description begins with the coarser structures and gradually passes to the finer ones, in order to point out more definitely that this organ is composed of a multitude of histological units. It will be apparent to the reader that our knowledge of the structure of the spleen is much more satisfactory than that of the function, but it is usually in this order that anatomy and physiology progress.

Framework of the Spleen.—If pieces of a fresh spleen are gently crushed between the palms of the hands in a stream of water, the pulp is soon washed out, leaving only the coarser network of fibres, or trabeculæ, the capsule, and the blood-vessels. When these are examined with the low power of the microscope, it is found that the trabeculæ are of uniform size and encircle spaces, each of which is about 1 mm. in diameter. This rough method of demonstration may be aided by macerating pieces of the spleen in water or in a solution of potassium hydrate, or by digesting them in a solution of pancreatin; but the specimens thus obtained are not much more instructive than those made by the simple water method. After repeated tests I finally invented a method by which the trabecular system of the spleen is demonstrated clearly and definitely.

The spleen is removed from the body with a portion of its mesentery, care being taken not to tear the capsule. It is kept completely covered with water at ordinary room temperature for a week or more, until the pulp is soft, the water being changed from time to time in order to prevent excessive putrefaction. When the pulp is soft the tip of the spleen is cut off and the pulp stripped out. The spleen is then filled with water and washed until the trabecular system and capsule is perfectly clear and clean. By repeated washings the framework of the spleen is finally clean, and it can now be strained, blown up, and dried. After the trabecular framework is purified in this way, it can be digested, stained, or treated with various reagents in order to determine the nature of the fibres of which it is formed.

The capsule and trabecular system being perfectly clean, it is to be stained with acid fuchsin and then thoroughly washed with alcohol. A tube is now tied into the cut end of the spleen and the specimen is kept distended with compressed air. After it is dry the mesenteric border and adjacent capsule are removed with a forceps and scissors, thus giving a most magnificent preparation. Fig. 4458 is from a section of dog's spleen prepared in this way.

Structure of the Capsule.—It is easy to show that the capsule of the spleen is composed of both white fibrous and yellow elastic tissues. A strip of the capsule boiled in dilute KOH will show the one, while digesting with pancreatin and further microscopic study will show the other. After the capsule of the spleen, the trabeculæ, and a piece of tendon have been digested in pancreatin for eighteen hours to remove all the elastic tissue, boiling them in HCl 0.5 per cent. or KOH 0.5 per cent. will dissolve the tendon in five minutes, the capsule in about twenty minutes, and the trabeculæ in about one hour. In each test a control section of the lymphatic gland shows that its reticulum is less resistant than are the fibrils of the capsule of the spleen. These tests, the value of which will be discussed later on, show that the capsule of the spleen contains, besides yellow elastic tissue, also white fibrous and reticulated. The white fibres can easily be recog-

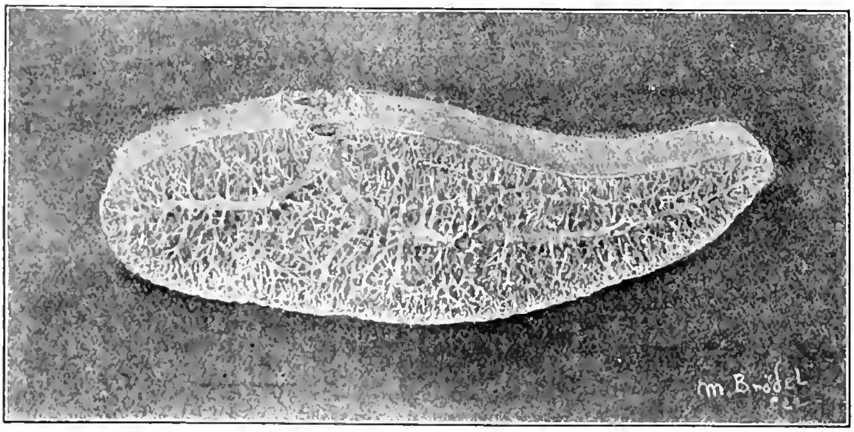

Fig. 4458.—Transverse Section of the Framework of the Spleen. Natural size. It shows the relation of the vein and the artery.

nized with the microscope by their wavy appearance and by their color, as well as by the great amount of gelatin which can be obtained from them when boiled. That it takes as much time to dissolve the capsule in boiling KOH or HCl as it does to dissolve a section of a lymphatic gland indicates that both are made up of the same tissues. That these two tissues are at least histologically unlike tendons is shown by their appearance under the microscope and by the fact that they will resist boiling acid and alkali at least four times as long as tendon does. From these observations I must conclude that the capsule of the spleen is composed of elastic, white fibrous, and reticulated tissues.

In the spleen of an ox macerated in water, digested in pancreatin, blown up and dried, the capsule is easily split into two layers—an outer which is composed in great part of white fibrous tissue, and an inner which appears to be of the same constitution as is the trabecular network. Between these two layers the lymphatics are located.

If a portion of the capsule of the spleen is first treated with hot dilute KOH, or is digested in pancreatin, and then stained and mounted in Canada balsam, it is found that the fibrils radiate toward centres from which the trabeculæ arise. Such a specimen is pictured in Fig. 4459. In case the preparation is treated with KOH the specimen thus obtained is composed of yellow elastic tissue, while if it is obtained through pancreatic digestion it is composed of white fibrous tissue and reticulum fibrils.

The three groups of fibrils forming the capsule of the spleen are all arranged after the same plan. When the white fibres and reticulum fibres are first removed by boiling the capsule in dilute KOH, leaving only the elastic tissue, a specimen is obtained which could easily be mistaken for the tissues destroyed, were it not for the chemical and color reactions, as well as the high refractive index of the elastic fibres.

Frozen sections of the spleen, which have first been macerated in water or in ten-per-cent. NaCl solution and then stained in hæmatoxylin, show the capsule and trabeculæ intensely stained, as all the non-striated muscle cells and elastic tissue are still present in them. This method is not suited to determine the character of the tissues constituting the capsule and trabeculæ, as the presence of all obscures the individual. When, however, the sections are first digested with pancreatin, it is found that the capsule is composed of delicate and wavy fibres, which in turn are arranged in heavier bundles; from these arise fine fibrils and anastomosing fibrils. That a number of white fibres are in the capsule is shown by the large quantity of gelatin easily obtained from it and by the bundles of wavy fibrils seen with the microscope. These bundles lie in great part immediately below the peritoneum, radiate toward the trabeculæ, and are continued into them. That the capsule also contains reticulated tissue is shown by the number of anastomosing fibrils present in teased specimens, as well as by the great resistance of the capsule shown when it is boiled in dilute KOH or HCl after all the cells and elastic tissue fibres have been removed by digestion with pancreatin. When boiled with dilute acid or alkali, as shown in Table I., the capsule proves to be much more resistant than is either a section of the lymphatic gland or a bundle of fibres from the tendo Achillis.

The conclusion to be drawn from these tests is that the boiling first removes the white fibres and leaves only the reticulated tissue, which finally falls into pieces. Although these tests are not absolutely definite, they at least make it highly probable that reticulated tissue exists in the capsule of the spleen. The fact that the fine anastomosing fibrils can be seen with the microscope in digested specimens is an additional argument in favor of this view. This question will not be completely solved until an extensive chemical study is made on these fibres obtained from different organs in addition to the invention of a satisfactory differential stain.

The group of the three kinds of connective-tissue fibrils then radiates toward centres, as shown in Fig. 4459. From these centres the trabeculæ arise and penetrate the spleen at right angles to the capsule. In general from four to six trabeculæ surround small masses of spleen

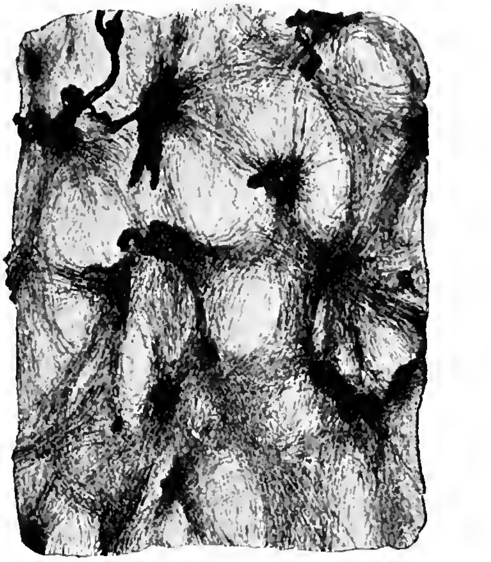

FIG. 4459.—Capsule of the Dog's Spleen Stripped Off Fresh and Digested in Pancreatin. Thoroughly washed in water and spread on a glass slide and allowed to dry. Stained with acid fuchsin and partly decolorized with picric acid. Enlarged 30 diameters. The trabeculæ are torn off at their capsular origin.

tissue, about 1 mm. in diameter. These masses I have termed the typical lobules or anatomical unit of the spleen.[1] They are well seen on the surface of fresh contracted spleens as slight elevations about as large as pins' heads. The great number of muscle cells within the trabeculæ makes the lobules immediately below the capsule protrude when they contract.

STRUCTURE AND ARRANGEMENT OF THE TRABECULÆ.—The trabeculæ in the capsule are composed of elastic, white fibrous and reticulated tissues, as well as great quantities of non-striated muscle cells.

The elastic fibres may be demonstrated by boiling the isolated trabeculæ with dilute KOH, but this is not a satisfactory method, for the elastic fibres separate and are easily lost. Henle's method[2] of treatment with cold dilute KOH and afterward washing with water is only fairly satisfactory, for it does not destroy completely the reticulum and fibrous tissue. To be sure, the elastic tissue prepared by Henle's method is easily recognized under the microscope by its high refractive index. Furthermore, the great destruction of the elements in isolating the elastic fibres by Henle's method makes it difficult to locate the part of the spleen from which the fibres have been obtained.

As regards the distribution of elastic tissue in the spleen, a decided step in advance has been made recently by Hoehl[3] in using Spalteholz's method of staining elastic tissue. By this method it is shown that there are numerous elastic fibres not only in the trabeculæ, but that they extend somewhat into the spleen tissue between the pulp cells. Sections in which the elastic fibres have been stained black by Spalteholz's method and the reticulum red with picrocarmine show that the finest elastic fibres never communicate with the reticulum.

After the cells and elastic fibres are removed from the trabeculæ, the reticulum and white fibrous tissues alone remain. To separate these two definitely again becomes the stumbling-block in connective-tissue study. That reticulum is present is shown by the fact that the fibres anastomose and by the great resistance of this tissue toward boiling KOH and HCl, as shown in the above tables. It takes more than twenty-two times as long to dissolve the trabeculæ than the tendo Achillis in one-half-per-cent. KOH, and six times as long in one-half-per-cent. HCl. To prove the presence of fibrous tissue is by no means as easy, for whatever reagent is used to dissolve the reticulum dissolves also the white fibrous tissue. Teased trabeculæ occasionally show bundles of wavy fibres which have all of the appearance of white fibrous

FIG. 4460.—Section of the Spleen Treated as that from which Fig. 4458 was Drawn. The vein had been injected with Prussian blue. Enlarged 8 diameters.

tissue. In case it is finally proved that reticulated tissue does not yield gelatin when boiled, the presence of gelatin will indicate the presence of white fibrous tissue.

Hoehl[4] has shown that the non-striated muscle fibres are embedded in a mass of most delicate connective-tissue fibrils, which, if I may judge from specimens he has sent me, appear to be reticulum fibrils. I have investigated non-striated muscle from the stomach, intestine, and uterus, and can fully confirm Hoehl's observation. It appears to me that the reticulum of the trabeculæ of the spleen may be considered as a sheath to the muscle, as is the case of non-striated muscles in other parts of the body. It is a very resistant reticulum, more so than that of the lymph follicle, and much more so than that of the pulp of the spleen.

All of the connective tissues and muscles which constitute the trabeculæ form the main skeleton of the spleen. From a number of estimations I find that there are from fifteen thousand to twenty-five thousand trabeculæ, each from 0.05 to 0.1 mm. in diameter, arising from the capsule of the dog's spleen to pass at right angles into the pulp. These many beautiful muscle strands outlining about twenty-five thousand subcapsular lobules pass into the depth of the spleen, anastomose and subdivide, and finally attach themselves to the walls of the veins as well as to the trabeculæ arising from the opposite side of the spleen.

The trabecular system of the spleen appears to be irregular in arrangement, but when examined closely it is shown that it surrounds distinct areas, about 1 mm. in diameter. Not only are these areas shown in the picture when the capsule has been removed, but they also appear as rounded elevations immediately below the capsule. This mottled appearance on the surface of the spleen is seen still better in the fresh spleen, as the contraction of the muscles causes the pulp between the trabeculæ to protrude under the capsule. When the artery of the fresh spleen is injected with an aqueous solution of Prussian blue, it will be noticed that the centres of these elevations are first injected, making the spleen mottled. The blue centres of these elevations gradually extend as the injection is continued, and finally flow together, when it is found that the fluid has entered the veins.

By comparing the specimens thus obtained, it is seen that we are dealing with an orderly arrangement of the spleen tissue which can easily be recognized with the naked eye. It is practically identical with the arrangement of that of the liver, and I shall speak of these anatomical units as the lobules of the spleen. *The anatomical unit of the spleen is a mass of pulp about one millimetre in diameter, with the main veins and muscle on its periphery and the artery in its centre.*

In turn the lobule is broken up into histological units, which I shall consider when discussing the termination of the arteries. If the pulp of the spleen is removed by washing it out and the trabecular system distended and dried, the lobules are seen outlined beautifully when the specimen is viewed as a transparent object. They appear five- or six-cornered, with darker points at about three of the corners, as is the case in the liver. These darker corners represent the position of the more important veins which encircle the lobule. But in addition to the trabeculæ which encircle the lobule, as shown in Fig. 4460, there are many other trabeculæ around the lobule, and a number of them penetrate it, although the greater number of the trabeculæ are on the periphery. The illustrations of the corroded spleen, as shown in Fig. 4458, do not show the lobules as well as Fig. 4460 does, for the former was drawn from a specimen in which the veins were not injected, while the latter is from a specimen in which they were injected. In case the veins are not injected but are only distended by the general distention of the whole organ, the tips of the veins blend with the trabeculæ and thus partly obliterate the sharpness of the lobule. In case the veins are partly injected, as in Fig. 4460, the lobule is outlined by the veins, while the trabeculæ which penetrate the lobule are also shown. Stained sections of injected spleens also bring out this point. Fig. 4460 shows beautifully the deep lobules as well as the ones immediately below the capsules. While there are from fifteen thousand to twenty-five thousand subcapsular lobules in the dog's spleen, there are from fifty thousand to one hundred thousand deep lobules, making the sum total of lobules between sixty-five thousand and one hundred and twenty-five thousand, or an average of eighty thousand. Lobules in any portion of the spleen can be seen very well in corroded specimens, either injected or uninjected, but they are somewhat obscure in an ordinary section, because the lobules are perforated by a number of trabeculæ. Yet if only the coarser arteries and veins are injected, the peripheries of lobules are outlined by the veins, while the main arterioles mark the centres of them.

We can therefore classify the trabeculæ as well as the veins as interlobular and intralobular; the interlobular veins and trabeculæ are closely related, while the intralobular veins and trabeculæ are not related.

With the naked eye the different kinds of trabeculæ cannot be observed (Fig. 4458) unless the veins are exceedingly well shown, but with a slight magnification the various kinds of trabeculæ are easily seen. Fig. 4460 shows this beautifully. The interlobular trabeculæ are here seen to surround in part the terminal or interlobular veins, a portion of them lie between the veins, while another portion of them perforate the lobule. Those which lie between the lobules together with the veins make the greater part of the network of the spleen, as shown in Fig. 4458. In Fig. 4460 the lobule is outlined by interlobular trabeculæ and veins, while the interior of the lobule is cut up into compartments by the intralobular trabeculæ. These intralobular trabeculæ communicate with one another to form a group of meshes within the lobule, each 0.2 to 0.3 mm. in diameter. So the lobule, which is about 1 c.mm. in volume, is subdivided into about ten parts by the intralobular trabeculæ. Within each of these subdivisions there is a fine venous plexus which extends in all planes throughout the lobule. Each of the meshes formed by the venous plexus is 0.05 mm. in diameter, and there are about six thousand of them within each lobule, or about five hundred million for the whole spleen. In a number of specimens the estimation of the histological units obtained by dividing the volume of the spleen by the cube of the diameter of the histological unit gave in each instance about five hundred million. The meshes formed by the venous plexus of the lobule are occupied by the spleen pulp, within the centre of which the terminal arteries end. This small mass of spleen tissue encircled by a vein with the terminal arteriole in its centre forms the histological unit of the spleen.

Reticulum of the Spleen.—I have shown above that the trabeculæ are composed in great part of a very resistant reticulum placed between the muscle cells. That this should be the case is not very remarkable, since Hoehl has shown that the non-striated muscle fibres in other parts of the body are enveloped in a most delicate and extensive network of reticulum fibrils. I have tested Hoehl's work and can confirm it in every respect as regards the sheath of non-striated muscle fibres. This envelopment certainly has the greatest meaning in aiding those cells to perform their function. Were they simply stuck together by a cement substance, it is very difficult to conceive how they could act so very delicately and also with so much power without pulling apart. But as it is, each cell lies within a basket of delicate reticulum fibrils, which acts as ligaments passing in all directions.

The reticulum fibrils in the trabeculæ must be viewed as the sheath of their muscle cells. It aids to tie them together. Since the trabeculæ are in strands the fibrils are also in strands, in order to give them their best support. The reticulum fibrils of the trabeculæ are more resistant when boiled in dilute HCl or dilute KOH than

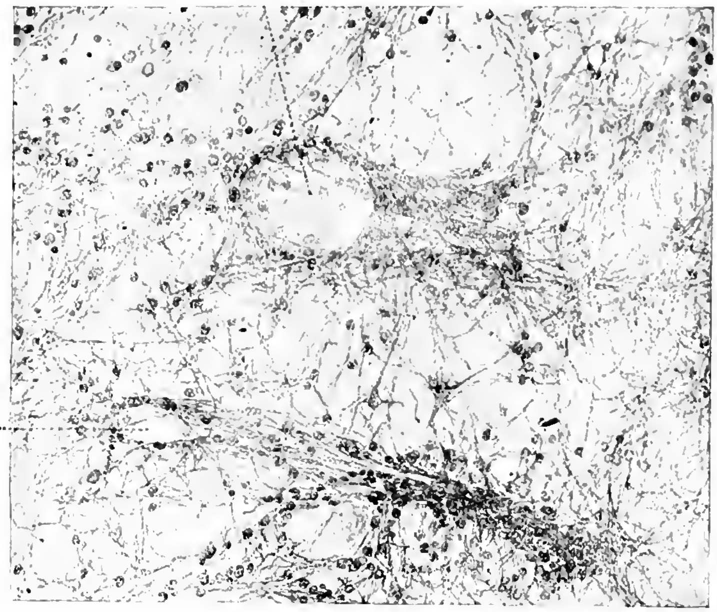

Fig. 4461.—Frozen Section of a Spleen made Œdematous by Injecting it with Colorless Gelatin. The section was then washed in warm water, which removed the gelatin and most of the cells, leaving the reticulum. Stained with gentian violet and mounted in glycerin. Enlarged 250 diameters.

are those of the capsule of the spleen or those of the lymph gland, as Tables I. and II. show. It is therefore a very tough reticulum.

In addition to this resistant reticulum of the trabeculæ, the lobule itself is filled with a very delicate reticulum, which is very easily destroyed and therefore hard to demonstrate by ordinary methods. I have noted in my earlier communication on reticulum that by the ordinary methods it was impossible to demonstrate the presence of reticulum between the trabeculæ within the spleen. At the same time Oppel[5] showed by using Golgi's method that the Malpighian corpuscle of the spleen and the tissue surrounding it was literally filled with a network of fibrils, which he termed *Gitterfasern*. Their appearance and arrangement at once showed that they must be reticular fibrils, but I was never able to isolate them by means of pancreatic digestion. In addition to Oppel's observation, we are all familiar with the reticulum of the spleen as seen in fresh as well as in hardened specimens. Hoehl has also shown us that when small pieces of spleen are washed for days in flowing water the cells are all washed out, leaving a beautiful network of fibrils, which he describes as reticulum. A frozen section of the spleen can also be washed out in flowing water, but the method is not satisfactory, as the section becomes matted together or is very liable to fall into pieces. When, however, a spleen is made œdematous by injecting it with gelatin, it can easily be cut by the freezing method, and the sections thus obtained are well suited for further study. The gelatin separates the tissue and holds everything in place. Such sections can be fixed with formalin and stained, or can be shaken out by simply placing them in warm water to dissolve the gelatin. They can be used for further tests with acid and alkali, or they can be digested with pancreatin.

When a frozen section of spleen made œdematous with gelatin is passed through formalin, it becomes well fixed and the gelatin can no longer be dissolved by heating or by digesting. Such a section stained with hæmatoxylin carmine, or a dilute aniline, gives most instructive pictures. The fibrils of reticulum are widely separated, upon them lie the fixed cells, and between them pass the blood-vessels. Within the gelatin itself are numerous free cells, and red blood corpuscles, proving conclusively that they are not within the blood-vessels. If, instead of hardening the section in formalin, it is placed in warm water to dissolve the gelatin, it is seen that the section becomes smaller in area, showing that the reticulum is elastic, but in so doing the gelatin carries out all of the free cells, leaving almost a pure reticulum. Such a section can be coaxed upon a glass slide, stained under the cover glass with acid fuchsin or with gentian violet, differentiated with picric acid, and preserved in glycerin (Fig. 4461). Such specimens are easily made, and they show perfectly the reticulum as demonstrated by Oppel and by Hoehl.

Further tests with pancreatin show that the reticulum of the spleen lobule is easily digested in it. The same is true if sections or blocks either of fresh or of hardened spleen are digested in pancreatin. In all cases the reticulum of the lobule is dissolved, but that of the trabeculæ remains. In pancreatin, then, this reticulum, as elastic tissue, dissolves. When, however, sections of reticulum are treated with dilute KOH, dilute HCl, or acetic acid, it at once swells, becomes transparent, while the elastic fibres show their usual reactions. With these reagents the reticulum shows its usual reactions. The reticulum of the spleen lobule is about as delicate as fibrin and at times I have thought that it is fibrin, but its distinct anatomical relation to other structures within the lobule proves that it must be constantly present.

The difference between the reticulum of the lobule and that of the trabeculæ is certainly most marked; that of the lobule is the least resistant reticulum known, while that of the trabeculæ is the most resistant. It only shows that there are a variety of reticula, and here we encounter side by side the two extremes. An analogous condition is found in fibrin. Newly formed fibrin is very easily digested, while fibrin from old fibrinous deposits is most resistant, not being digested in pepsin or pancreatin nor dissolved in strong acids. It is also not possible that the two reticula found in the spleen could be two varieties of the same thing, as it is impossible to conceive of the reticulum of the lobule shifting to become the reticulum of the trabeculæ.[6]

The main reactions of the connective-tissue fibrils are expressed in the following table:

TABLE II.

	Yellow elastic.	White fibrous.	Reticulum ordinary.	Reticulum from lobule of the spleen.
Boiling dilute HCl or KOH	0	+	+	+
Pepsin digestion	+	+	+	+
Pancreatic digestion	+	0	0	+
Maceration	+ (?)	0	0	+
Gelatin	0	+	+(?)	(?)
Reticulin	0	0	+	(?)

0 = not changed or no.
+ = dissolved or yes.

THE ARTERIES OF THE SPLEEN.—The arterial system of the spleen is arranged, as in all other organs, in such a manner that equal parts of it will receive equal quantities of blood during a given period of time. So definite is this adjustment that in studying organs we must always look for terminal branches which supply the final units of tissue, as is the case in the villus of the intestine. These tissue units are piled upon one another in the solid organs much like the grapes in a bunch, but in turn they may be clustered around centres as are the bunches of grapes upon a vine, which again may be repeated many times like the vines in a vineyard. This is the arrangement in the spleen, and when it is studied embryologically as well as physiologically it is found that it could not well be otherwise.

Without discussing the question extensively I allude to the many researches of Ludwig and his pupils as well as to the brilliant studies of Thoma bearing upon this question. Ludwig has shown us that in the circulation through an organ no part of the organ is favored more than another, while Thoma has demonstrated the conditions which regulate the size of the arteries not only in the embryo but also in the adult. Ignoring the causes which produce the first growth of the capillaries, Thoma's work establishes the fact that in a given vessel there is a relation between its lumen and the circulation through it. Any factor which makes the blood flow more rapidly will cause the vessel to enlarge, while anything which diminishes the circulation will make the vessel become smaller. This law is constantly at work not only in increasing the number and size of the blood-vessels in the growth of an organ, but also in diminishing and reducing them. It follows that in a finished organ the arteries are beautifully distributed according to system throughout it and that the forces which produced this relation are ever ready to correct little difficulties which are constantly arising.

The main trunk of the splenic artery gives off a number of branches, which, according to their size, are distributed to proportionately large parts of the spleen. In general, throughout the spleen the arteries are separated as far as possible from their corresponding veins, but at their points of entrance a number of the arteries are located close to the veins. This must be due to a secondary shifting of the large vessels in their development, as is also the case in the lung and the liver.

After the arteries enter the spleen their main trunks remain on the proximal side of the veins, as Fig. 4458 shows. In general, they lie midway between the larger veins and the capsule. These primary branches in turn give rise to branches of the second order, which pass directly toward the capsule, there passing to the proximal side of the spleen, crossing the large veins, but keeping away from them as far as possible, and give rise to all of the lobular arteries of the spleen.

The spleen of an animal killed by bleeding is found to be contracted and relatively pale after having been exposed to the air for a very short time. Its surface is rough, due to a protrusion of the lobules immediately below the capsule. If the artery of a spleen which shows these characteristics is injected with aqueous Prussian blue, it will be found that the centres of the lobules below the capsule first turn blue, thus showing conclusively the relation of the artery in the lobule. From these many blue points in the centres of the lobule the blue spreads as the injection is continued until their peripheries are reached. At this time the blue lobules coalesce and the Prussian blue appears in the veins. As soon as the blue has once entered the veins, secondary injections take place through the veins in distant portions of the spleen, giving pictures the reverse of the ones just described.

The lymphatic tissue encircles the arteries, increases at points into marked follicles, and accompanies them until they reach the histological units, where they form the splenic ellipsoids. The thickness of this lymphatic sheath varies very much in different spleens, and often in different portions of the same spleen. Whether these variations are transient or permanent in a given spleen is difficult to determine, but it is certain that in all cases the lymphatic follicles, cords, and ellipsoids lie around the artery and in the centres of the lobules and pulp cords. The relation of the artery and the vein to the lymphatic tissue in the spleen is identical with that of the lymphatic gland, as recently shown by Calvert.[7] The spleen structure differs, however, from the lymphatic gland in that its lobule contains no lymphatic channels like the follicle, but in their stead there is a marked and peculiar plexus of veins, which surround the lymphatic tissue of the arteries to complete the spleen lobule. In other words, the spleen can be viewed as a modified lymphatic gland without lymphatic channels.

It is appropriate at this place to speak of the lymphatic channels of the spleen, because in their true sense—*i.e.*,

FIG. 4462.—Section of a Spleen in which the Veins had been Injected with Aqueous Prussian Blue. Canada balsam preparation. Enlarged 30 diameters.

in their relation to the Malpighian follicles—they do not exist. Although nearly every text-book on histology states that the lymphatic channels exist in the spleen, I must assert that the books are wrong. Nor can I find any proof of their existence in reliable literature, nor by hundreds of injections of many kinds made by me. To be sure, the capsule of the spleen of the ox, pig, and horse contain large lymphatic channels which enter the spleen along the trabeculæ, but I could not trace them back to the lobule. In the dog a few lymphatic channels are occasionally seen at the hilum of the organ, but these do not penetrate the spleen, much less do they meet the Malpighian follicle. Moreover, most careful analysis of the lobule of the dog's spleen never shows their presence, unless we consider the intestinal spaces lymphatic radicals which never collect into efferent vessels but enter the veins at once.[5]

THE VEINS.—The spleens of most dogs have eight large veins emerging at the hilum, although frequently there is a tendency for two or three of them to unite within the substance of the large end of the spleen before they pass out of the organ. These eight main trunks pass deep into the splenic tissue and ramify on the distal side of the artery in all directions, as the section pictured in Fig. 4458 shows.

The first group of branches, those of the first order, are all distributed in the flat plane of the spleen. The veins of the second order arise at right angles from this first group and pass directly toward the capsule. The terminal branches of the second group become the interlobular veins (Fig. 4460).

As the large veins enter the spleen its capsule accompanies them and in a measure helps to form their walls. The walls gradually thicken and from them arise numerous trabeculæ which are directly continuous with the general trabecular network of the spleen. As the vein divides and subdivides, the trabeculæ attaching themselves to them increase in number, so that by the time the interlobular veins are reached the small size of the veins makes it appear as if they ran within the trabeculæ.

Thus the veins show a definite relation to the trabeculæ throughout the spleen until the lobule is reached. The intralobular veins not having a muscular wall must communicate with the interlobular veins through numerous openings in their thick sheaths, as is shown by the opening pictured in Fig. 4462. The larger veins, *i.e.*, veins of the second order, also receive collecting veins directly from the intralobular plexus. All the systems of the veins are shown in Fig. 4463. In this figure the veins of the first order are cut transversely; those of the second order give rise to the interlobular veins; the intralobular venous plexus is shown opposite, at *L*, while the intralobular collecting veins are shown at *L'*. The relation of the trabeculæ to the veins is such that when the veins and trabeculæ are stretched the larger veins are distended, as a number of the figures show.

This arrangement must be of the utmost physiological importance, for increasing the tension of the pulp of the

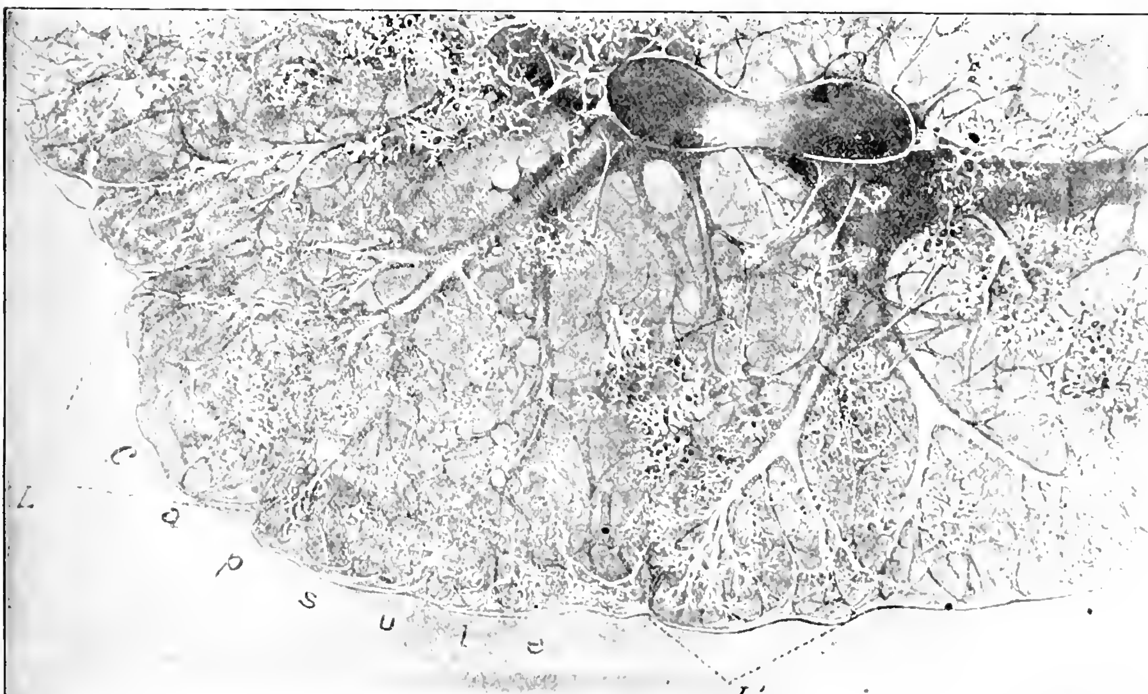

FIG. 4463. Section of a Spleen in which the Vein had been Injected with Celloidin Colored with Prussian Blue. The whole spleen was macerated for weeks in water, then digested in pancreatin, washed, stained, distended, and dried. The dried spleen was next sectioned and mounted in Canada balsam. Enlarged 16 diameters.

spleen, either through an increased quantity of fluid within the pulp or through a contraction of the trabeculæ and capsule, will favor the flow of blood toward the vein and into it.

Preparations of the spleen made by maceration, cleansing, distention, and drying show the general arrangement of the trabeculæ to the veins. With the naked eye the veins can be followed to the interlobular spaces. Low powers show this relation of the veins to the lobule bet-

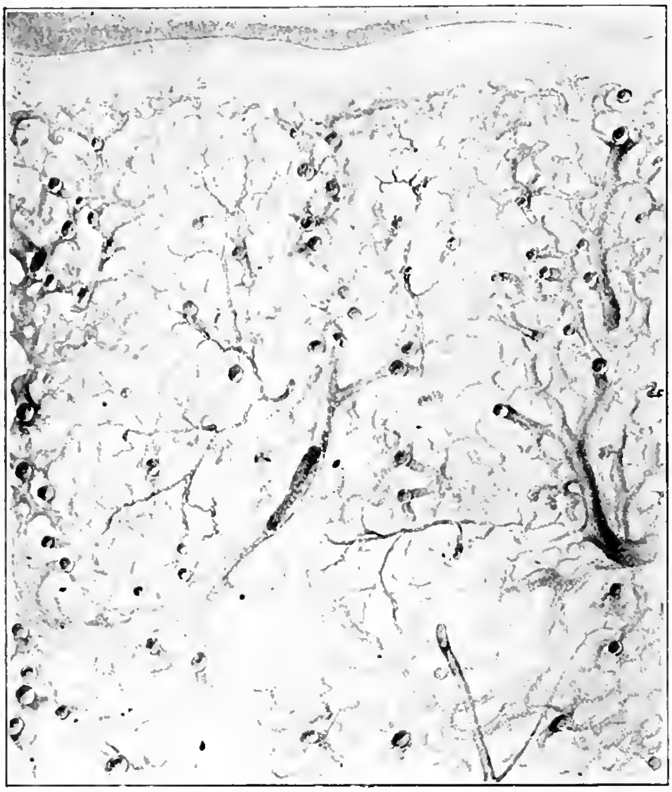

FIG. 4464.—Double Injection of the Spleen with Prussian Blue into the Vein and Carmine Gelatin into the Artery. At many points the injection of the artery is more complete than is shown in the figure, the entire field being tinged red. Enlarged 10 diameters.

ter (Fig. 4460), yet it is impossible by this method to follow with certainty the smaller veins between the lobules to the capsule. At the main junctions of the trabeculæ with the veins the tissues are more or less matted together, and an attempt to separate them without special methods always leads to some confusion. Ordinary injections of the spleen do not give better specimens, and for a long time I had to rely on sections of hardened spleen which had been injected by the ordinary method. Such specimens do not lead to good results, as the great quantity of colored veins in a thick specimen obscures the larger vessels, for at no time do any number of them lie in the same place. Finally, however, I obtained most definite specimens by macerating spleens after the veins had been injected with either colored celloidin or agar-agar. Both of these substances will not dissolve when the tissue is macerated or when it is digested in pancreatin. The agar can easily be forced throughout the whole venous system, and, if too much pressure is applied, into the tissues, while the celloidin flows with difficulty and under no condition will fill completely the venous plexus of the lobule.

Fig. 4463 is from a specimen injected with celloidin colored with Prussian blue digested with pancreatin, washed, and slightly tinged with acid fuchsin. It was next injected and dried, then cut into sections and mounted in Canada balsam. It shows most beautifully the interlobular veins and the intralobular venous plexus. Only at exceptional points is this plexus injected, and in numerous sections the larger veins, the interlobular veins, and the trabecular system alone are shown. In sections parallel with and immediately below the capsule the lobules form a beautiful honeycomb arrangement with the larger interlobular veins at the point of junction of several lobules. The veins now leave the trabeculæ and enter the lobule to form the intralobular venous plexus (Fig. 4464). The main venous branches upon entering the lobule give rise to numerous smaller branches, which anastomose with one another to form the intralobular venous plexus.

Specimens obtained by digesting with pancreatin a spleen in which the veins have been injected with colored celloidin outline most beautifully the spleen lobules. They are about as regular in shape and arrangement as those of the liver, and each is encircled by about three terminal interlobular veins, which are set equidistant from one another and lie within trabeculæ. The walls of the branches which arise from the interlobular veins to penetrate the lobule are formed by a delicate network of reticulum fibrils lined by a layer of peculiar spindle-shaped endothelium cells.

The spleen shows much more beautifully than any other organ the value of fibrils in the construction of a skeleton in which the various structures are suspended. This skeleton not only acts as framework for the larger veins, lobules, and muscles, but is also most delicately adjusted to the structures of the lobule. The arrangement of the whole skeleton is such that a contraction of the muscles (trabeculæ) will compress the lobule (pulp), at the same time pulling open the larger veins. When the contraction of the trabeculæ and capsule is at a maximum the larger veins are also compressed. This mechanism thus aids the circulation from the pulp to the smaller veins and from them to the larger ones. Within the lobule the elastic network of reticulum not only empties the intralobular plexus, but also aids to force the red blood corpuscles and plasma which have escaped into the interstitial spaces back into the veins.

If a portion of a spleen is made partly œdematous by injecting neutral gelatin into a few of its arteries, most instructive specimens are obtained by further injecting the whole venous system with a weak solution of nitrate of silver. A successful specimen made in this way shows the cells lining the veins, outlined and stained, throughout the whole organ. In the contracted portion of the spleen the veins are shown in a collapsed state, while in the œdematous portion they are shown distended. From specimens made in this way I find that the whole venous tree, up into the lobule, is lined by a complete layer of endothelium cells. From this portion of the venous tree no extravasation of blood can take place, as repeated injections have shown. When, however, the endothelial lining is followed into the lobule, it is soon seen that the walls of the veins are not by any means complete, but there are numerous stomata between endothelial cells which are greatly increased in size when the lobule is distended. A given vein followed from an interlobular vein into the lobule soon loses its sharp endothelial lining. At first, in the interlobular collecting veins, the outlines of the cells are sharp and line the whole vein, in either collapsed or distended condition, but as the vein breaks up into the venous plexus the cells no longer line the whole vein. The transition from the complete endothelial wall to an incomplete one takes place in the collecting veins of the lobule, and no complete walls are found within the intralobular plexus.

With the change from a complete endothelial wall to an incomplete one the forms of the cells change also. When the wall is complete the endothelial cells have the usual and well-known form, but as the wall becomes broken the cells at first are irregular, flat protoplasmic masses, sometimes sharply outlined on the side toward the complete wall, but usually irregular in all directions. Soon, however, the cells change their form into a long spindle-shaped mass with rounded ends, with the nucleus protruding on one side of its body, as is well pictured in Henle's "Anatomy." These have been described as muscle cells, and when isolated look much more like them than those pictured by Henle. Yet their position and relation to the perfect endothelial walls lining the collecting veins show definitely that they are endothelium. These long spindle-shaped endothelial cells do not overlap at all in lining the veins of the intralobular plexus. Sometimes two nuclei are seen side by side, but in thin sections of organs made œdematous with gelatin, frozen, cut, and hardened in formalin, they are found to be fairly numerous. The spaces between them in distended organs are considerably larger than the diameter of their nuclei, large enough to allow cinnabar granules to pass into the tissue with ease when injected into the veins, but too small to allow many ultramarine blue granules to escape.

The Lobule of the Spleen.—It has been shown above in the study of the arteries, veins, and trabeculæ that each of these systems is ultimately related to a portion of spleen substance, always of about the same volume, which I have termed the anatomical unit or the lobule of the spleen. These units are outlined only by the larger trabeculæ with their enclosed veins, and not by a membranous layer of connective tissue, as is the case in the lobule of the pig's liver. So in sections it is almost impossible to detect the lobule because in the mass of splenic tissue there are seen only sections of the scattered trabeculæ, some of which are within the lobule.

With care and some imagination the lobule may be outlined in a thin section of spleen after the veins have been injected. Especially is this true if the section is immediately below and parallel with the capsule. In specimens so made the lobules are cut transversely and are outlined by the larger veins and trabeculæ. Yet a number of fairly large veins and smaller trabeculæ enter the lobule, and their section aids to obliterate it. When, however, the veins are injected with coarse granules which do not enter the smaller veins easily, thick sections show the lobules very clearly. Such a section is given in Fig. 4464. In this specimen the lobules, both peripheral and deep, are shown throughout the spleen. This method of preparation permits of the study of the lobules themselves more carefully than do the common specimens, the latter, however, giving more clearly the outlines of the lobules and their relation to one another.

The study of the artery also aids to define the lobule, as its main terminal branches always lie in the centre of it. The arterial injections always show the lobules best when the tissues have first been well distended with a fluid. In the specimen from which Fig. 4464 is taken this was done by means of the diffusion of the gelatin throughout the tissue after having been injected into the vein. The same result was accomplished in the second specimen by ligating the splenic vein in an animal half an hour before killing it. By so doing the lobules are all distended with blood and the main structures within them are spread apart. After this the artery was next injected and thick sections of the fresh spleen were placed in ten-per-cent. NaCl to extract the blood. Specimens made in this way show the distribution of the artery in the lobule most beautifully.

Not only does the artery mark the lobule by passing in through its centre, but it is especially well defined where the arterial sheath of lymphatic tissue becomes enlarged to a Malpighian follicle. These follicles usually lie at the point where the artery enters the lobule, but in rare instances they may extend well into the lobule or they may be so large that at the point of their location the whole lobule is not only filled but distended. This is especially the case in spleens which are empty and collapsed.

With thick sections of injected spleens the lobule is again well defined, confirming in every respect the results obtained from corrosion specimens. That this is so is of the utmost importance in outlining the lobules, because the tissues of neighboring lobules run together, and because the main trabeculæ, veins, and arteries undergo further branching over and into the lobules. A similar branching takes place among the interlobular veins, bile ducts, and arteries of the liver. At the middle of the lobule of the liver there are on an average three interlobular veins, while at the distal end or tip of the lobule there are six. Furthermore, the architecture of the liver lobule is by no means as simple as it is usually pictured; in fact, its very existence was not fully established until nearly two hundred years after it was described by Malpighi.

Were it not that the section of the bile duct is so characteristic, we would have as much trouble in locating the liver lobule in most animals as we have in locating the spleen lobule.

Throughout the lobule there is a beautiful venous plexus which is suspended in a coarse network of trabeculæ penetrating the lobule. These trabeculæ are solid, having no veins within them but toward the periphery of the lobule they usually accompany the collecting veins arising from the venous plexus. On an average there are nine of these intralobular collecting veins in each lobule. The distances between them are equal and they divide the lobule into nine pyramidal parts, within the centre of each of which parts there is a branch of the lobular artery. In a measure this arrangement is shown in Fig. 4464. If the subdivisions of the lobule marked by the intralobular veins were more definite, I would be inclined to consider them the lobules of the spleen, as they possess all the characteristics of lobules. But the extreme difficulty in demonstrating their presence by the different methods at our disposal, as well as the fact that the greater masses or lobules always exist and can be demonstrated with much greater ease, is the reason why I consider the larger the units, and the smaller ones the subdivisions of the units.

But if we did consider the subdivisions to be the lobular units, we should still not be at the end of our difficulty, for they are again cut up into compartments by branches of the intralobular collecting veins which finally arise from the venous plexus. The venous plexus, however, is definite and constant. This last surrounds small masses of spleen tissue, in the centre of which is the final arteriole. This mass, with the end of the artery in its centre and the venous plexus around it, I shall term the histological unit. Within it lies the whole mystery of the spleen.

The spleen is composed of many histological units which are arranged in great clusters within the anatomical units or lobules. The lobules are repeated a sufficient number of times to form the whole spleen.

The Histological Unit or Pulp Cords.—The histological units occupy all the space of the spleen with the exception of that occupied by the Malpighian corpuscles and their extension into the lymphatic tissue which accompanies the arteries. The boundaries of the units being outlined by the veins of the intralobular plexus, which pass in all planes, are not separated from one another any more than are the holes in a sponge, although these are outlined by the sponge substance. The units together, as well as the veins, form a ramifying network, the two together filling all the available space.

Fig. 4463 is a low-power drawing of the network of veins within the lobule, *L*, the meshes of which are filled with the histological units or pulp cords. In Fig. 4462 the veins and units are shown with a higher power. As the veins are emphasized in this drawing, the units appear as islands, but it is easy to imagine them communi cating with one another between the meshes of the vein plexus lying in a deeper plane. Fig. 4464, which is still more highly magnified, shows the units as a plexus of the spleen pulp marked by the sections of the intralobular veins. When the boundary lines of the units are emphasized by examining with low powers thick sections which have been stained intensely, the veins are seen to outline the histological units as distinct islands. Thinner sections with higher powers, however, show that the units communicate with one another very freely and are also outlined by the sections of the veins of the intralobular vein plexus, as shown in Fig. 4465. The separation of the histological units and their relation to one another is a repetition on a smaller scale of the relation of the anatomical units or of the lobules.

Fig. 4462 is from a specimen in which the veins had been filled by an interstitial injection of aqueous solution of Prussian blue. In all specimens made in this way the blue fluid passes directly into the intralobular vein plexus and outlines the histological units. Interstitial injections of other organs usually fill the lymphatic channels, in case they exist, and in the spleen the anatomical arrangement of the venous plexus is similar to that of the lymphatics in other organs. This fact is remarkable, and although it may suggest ideas regarding the circulation through the spleen, it does not help us much regarding its anatomy, because we do not know the anatomy of the lymph radicals. When the veins of the spleen are filled either by means of interstitial injection or by injection into the main veins, the fluid never passes over into the arteries. This has been observed repeatedly by many investigators and appears to show conclusively that there is no direct connection between the arteries and veins.

The specimen from which Fig. 4465 was drawn was made by injecting chrome yellow suspended in gelatin into the vein until the spleen was distended to its maximum, and then an aqueous solution of Prussian blue was injected into the artery. In specimens made in this way the spleen is distended to its maximum with gelatin, with yellow granules in the veins and a blue precipitate in the artery. In the portion of the section drawn the arterial injection did not pass beyond the terminal arteries, but in many other portions of the specimen it did.

By this method of procedure there can be no doubt whatever in determining arteries from veins. In case the whole injection is made with a colored fluid into the artery, it is usually very difficult to determine whether or not a certain vessel is an artery or a vein, and in case it is a vein whether or not it had been injected through an artery in the immediate neighborhood. To illustrate: If an ordinary spleen, hyperæmic at points, is injected with Prussian blue through the artery, it is found that when the injection is complete there is usually much extravasation of fluid. Arising from these extravasations there are many injected veins, from which neighboring veins, including the intralobular plexuses, are injected. Of course, the arteries in portions of the spleen with secondary venous injections are also filled with fluid of the same color, and thus false conclusions are often drawn. Such specimens must be viewed as double injections with fluid of the same color, and are of little value in studying the relations of the blood-vessels of an organ, especially of the spleen.

To mark definitely the veins of the intralobular plexus, it is desirable to employ substances which will fill these veins and go no further. Ultramarine blue is an excellent substance for this purpose, as few of its granules will pass over into the tissues. Yet for purposes of double injection the color is wrong, for in all instances aqueous Prussian blue is the best for the artery. On this account I used most frequently chrome yellow granules in gelatin for the veins and Prussian blue for the arteries. After the spleen has had its veins all filled with the yellow granules suspended in gelatin, the gelatin passes over into the tissue, leaving the granules in the vein, for its walls act like a sieve. If the arteries of a specimen prepared in the above-described manner are injected with a solution of Prussian blue, but little of it enters the veins; nor can secondary injections of the spleen take place through the veins, as all of them have been plugged by the chrome-yellow.

A spleen having been made œdematous by the extravasation of the gelatin, by injecting it as described above, is easily cut into thin sections on the freezing microtome, either fresh or after it has been hardened in formalin. Such sections may be treated in various ways and are most instructive. They always have their veins decidedly marked with the yellow granules, which is of greatest importance in studying sections of the spleen. Repeated tests have shown that veins are very characteristic and need not be confounded with the *capillaries* or *ampullæ*, as I shall show presently.

Sections of the intralobular venous plexus are shown in Figs. 4461 and 4465, which are from specimens prepared in various ways. The figures show sufficiently the nature of the walls, the intralobular veins, venous sinuses, or spleen sinuses, as they have been termed. By injecting dilute solutions of nitrate of silver into the veins, endothelium cells are sharply outlined throughout the interlobular veins and fairly well in the intralobular collecting veins. From now on throughout the intralobular venous plexus the cells lining the veins no longer make a continuous layer. They become spindle-shaped with rounded ends, their nuclei protruding at their sides, as described by Henle. When the veins are collapsed these cells come in contact with one another, and in sections look much like non-striated muscle fibres. With the veins distended, however, the cells separate, leaving wide openings between them, which are large enough to allow cinnabar granules to pass through them with ease, but not large enough to allow ultramarine-blue granules to pass through freely. Although the blue granules are smaller than red blood corpuscles, they have sharp edges which certainly do not favor their passage through the openings in the walls of the veins, which are considerably larger than the diameter of the granules. The openings between the endothelial cells in the veins may be also shown by ligating the splenic vein in the living animal (Thoma). At first the spleen becomes hyperæmic, and sections at this stage show that all the blood is lodged in the veins and but very little in the tissues. After a greater length of time the veins become enormously distended, and then the blood begins to pass from the veins over into the tissues of the spleen pulp or the histological units. This experiment in itself is a strong argument in favor of a closed circulation through the spleen, for were it otherwise the blood would begin to accumulate in the tissues long before the veins are distended to their maximum. The pictures obtained after tying the veins all speak most strongly in favor of the idea that the blood in the spleen pulp extravasated from the veins and not from the arteries.

At any rate, both experiments and specimens show that the endothelial lining of the venous plexus is very incomplete, having openings between them large enough to allow the passage of red blood corpuscles with ease, and of course blood plasma with the greatest freedom. These openings are the largest when the spleen is distended to its maximum, and smallest when it is completely contracted. The two pictures obtained by examining distended and contracted spleens are so different that it is difficult to recognize that both are from the same organ. We are all familiar with sections of contracted spleens, but the sections obtained from a distended spleen are certainly a great surprise to one who has not seen them before. The most instructive specimens are made by injecting the veins of a portion of the spleen with ultramarine-blue gelatin, leaving the remaining portion uninjected. In the injected portion the tissues of the histological units are distended with the gelatin, while the blue granules remain in the veins. At the junction of the injected portion with the uninjected all gradations may be seen, which when put together give the idea that the cells have been washed out of the part distended. This interpretation is out of the question in this case, as the spleen substance has simply been distended with gelatin and all of its tissues have been held fast and fixed by the hardened gelatin.

Henle washed out the spleen by a long-continued artificial circulation of a solution of sulphate of soda through the artery. If the circulation is continued for half an hour or longer, the spleen loses its red color, becomes pale, distended, and very œdematous. The first fluid which comes from the veins has in it many red corpuscles, but as the spleen becomes paler and paler they gradually diminish in number. This experiment appears to prove that the blood-vessel system of the spleen is open and that the circulation passes through the spaces in the pulp. For a long time this argument seemed incontestable to me, and it, with another and apparently contradictory experiment, showed that the mystery had not been fully solved. Ten years ago I found that when cinnabar gelatin is injected into the artery with a pulsating pressure for a long-continued time, most of the cinnabar passed over into the intralobular venous plexus and not into the tissues of the pulp, as it should were the circulation through the spleen open. While Henle's experiment speaks for an open circulation, this experiment calls for a closed one.

I have repeated Henle's experiment many times, and am now fully convinced that he never washed out the pulp cells at all, but only washed out the cells and red discs which were lodged in the veins. In addition to this, he made the spleen œdematous, which in all cases appears "washed out." After the artificial circulation has been carried on through the spleen for hours, the pulp spaces of the histological units have within them just as many cells as are present when the œdema is produced by a simple injection of gelatin into the veins. In the latter instance the cells certainly were not washed out, as the gelatin simply passed into the tissues and after hardening held everything in place. Furthermore, in numerous tests I have never succeeded in removing the cells from the pulp by means of artificial circulation. Fig. 4461 is from a frozen section of a spleen made œdematous by injecting gelatin into the vein. The section was then placed in warm water to dissolve the gelatin, and then shaken a short time. Most of the cells have been removed. Further shaking would destroy the section entirely.

Reticulum of the Histological Unit.—That the framework of the pulp is made up of anastomosing fibrils which must be viewed as a variety of reticulum has been shown sufficiently above. At present I shall consider the arrangement of this reticulum within the lobule. In the description of the delicate reticulum fibrils of the lobule the terms reticulum of the lobule or of the pulp are used, while the tougher and more resistant reticulum of the capsule and trabeculæ is referred to as the reticulum of the trabeculæ.

The reticulum of the lobule forms a delicate network throughout the lobule, which in turn is suspended within the meshes of the network formed by the trabeculæ. The main strands of the fibrils accompany the vein plexus as pictured by Oppel. When sections of a fresh œdematous spleen are washed in water to remove most of the cells and then tinged with picric acid, the same picture is seen as that gotten by Oppel by using Golgi's method. The main strands of the reticulum accompany the interlobular venous plexus, while a more delicate network with more open meshes extends throughout the histological unit. In the centre of the unit the network becomes more dense again, which marks the position of the terminal artery with its accompanying ellipsoid lymphatic tissue.

Within the meshes of the reticulum are located all the cells known as pulp cells, *i.e.*, free cells including all the elements of the blood, giant cells, pigmented cells, and the fixed cells, which are more or less spindle-shaped. Many of the multipolar cells are only such in appearance, as their prolongations are the reticulum fibrils upon which they lie. Fig. 4461 is from a spleen partly washed out; it shows only the cells which are more firmly attached to the reticulum.

The reticulum fibrils are very extensible as well as elastic. The fibres may be stretched at least to twice their former length and when liberated will immediately rebound to the position they occupied before stretching. If a spleen is distended to its maximum by injecting it full of gelatin, it is found that all of the dimensions of the spleen have been doubled, as the spleen has increased its volume eight times. After the gelatin has hardened the spleen can be cut into sections on the freezing microtome and further experiments made upon them. When the section is placed in warm water to dissolve the gelatin, it is found that all its dimensions shrink to one-half. In other words, removing the gelatin allows the section to take the form it possessed before the spleen was injected. The reticulum is under no tension when the spleen is contracted to its maximum. When the spleen is distended the least its reticulum is stretched.

That the shortening of the section, when treated with warm water as described above, is due to the elasticity of the reticulum of the pulp and not to that of the structures of the trabeculæ, is proved by the fact that all the trabeculæ have been cut into small blocks in the sections. The small blocks of trabeculæ can no longer influence the dimensions of the section, for all of their main attachments have been broken. The trabecular network and capsule of the spleen are, however, very elastic, but the experiments with the œdematous section exclude these factors.

Fig. 4461 is from a section of œdematous spleen, the gelatin having been removed with warm water. The bundles of fibrils have taken on their natural shape, leaving a considerable lumen to the vein. Any further reduction of the meshes of the reticulum could be brought about only by external force, such as contraction of the trabeculæ in the living spleen. At any rate, it appears as if any marked distention of the spleen lobule can be brought about only by stretching the reticulum fibrils, and that these in turn are constantly pressing upon the fluids and elements within the meshes. In so doing the only outlet for them is through the vein, and this is favored by the openings in the vein walls. If the lobule is further distended the reticulum is stretched still more, and the veins, as well as the openings within their walls, are made larger. Everything, then, seems to favor the flow of fluid and cells from the spleen pulp into the veins when the pulp has become distended.

Henle has described spiral fibrils around the smaller veins in the spleen. In searching for them I have used his method over and over again, and occasionally I have obtained specimens which confirm his observations. It appears to me that the spiral fibrils which he describes are the reticulum fibrils around the larger veins, for only at these points have I been able to find them in specimens treated with KOH. I have already stated on a previous occasion that dilute HCl and KOH solutions do not cause white fibrous nor reticulated tissues to become transparent and swell when they are under tension. At the point where the larger veins (intralobular collecting veins) leave the lobule, the opportunity to stretch the reticulum surrounding them is extremely good while the specimen is being treated with KOH, because a pressure upon the cover slip will cause the trabeculæ to separate. These collecting veins are then stretched, as they are frequently located at the junction of two trabeculæ. Although, according to Hoehl, some elastic fibres leave the trabeculæ to enter the pulp, I do not think that Henle's spirals are anything but reticulum. If it were not difficult to obtain pictures like Henle's, the question could be easily settled.

The reticulum of the histological unit not only encircles the vein but extends to the artery, and in so doing passes through the lymphatic tissue surrounding it. If the reticulum is followed into the lymph follicle, it is found that the fibrils of the pulp are directly continuous with those of the follicle. Whether or not the reticulum of the follicle of the spleen gives the same reactions as that of the pulp cord, I have not been able to determine.

The Arteries Within the Lobule.—After the artery of the spleen has divided and subdivided a number of times, a final branch enters the base of each lobule, passes through its centre, and gives off numerous branches which radiate toward the periphery of the lobule (Figs. 4464 and 4466). In all there are eighty thousand lob-

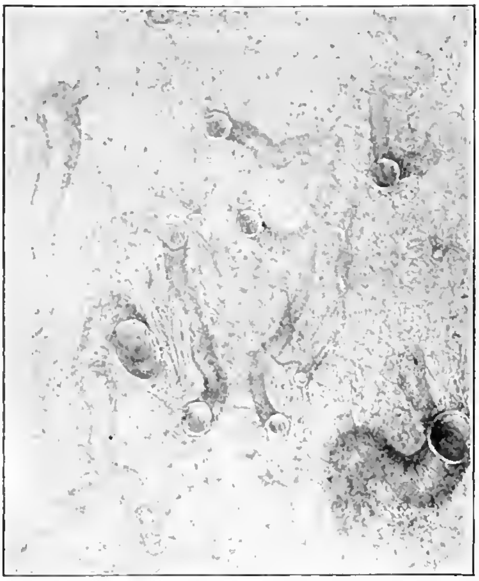

FIG. 4465. Section of a Spleen the Veins of which had First been Injected with Chrome Yellow Suspended in Gelatin. The gelatin formed an œdema and the yellow granules remained in the vein. The artery was next injected with an aqueous solution of Prussian blue. Enlarged 80 diameters. At the point from which the drawing was taken the injection in the artery did not reach the vein.

ules, which are piled upon one another in such a manner that their bases point toward the nearest main trunk of the artery. The term base is arbitrary, not being the largest side of the lobule; in the case of the deep lobules the "base" is as large as any other side; while in the subcapsular lobules it is, in fact, the smallest side. In spite of this, however, it is well to consider the base the side of the lobule, the side that is most firmly attached in case they are separated from one another. In other words, as in the liver, in the lung, or in the intestine, the base is the proximal side of the anatomical unit. Within the lobule the long slender artery gives rise to about ten main branches, which are located in the centres of each of the subdivisions of the lobule outlined by the intralobular collecting veins. Finally, the smaller branches run in the centre of the pulp cords and each artery terminates in the centre of the histological unit, as shown in Fig. 4466. As the subdivisions of the central artery of the lobule pass to their destination, they are seen to curl under and over the veins of the intralobular venous plexus, remaining as far as possible from the veins. Their course in the pulp cords is the same as that of arteries of the lymph cord of a lymphatic gland.[9] The relation of the final artery to the intralobular veins surrounding the pulp cords is again identical with the relation of the artery to the vein in the lymphatic gland, as described recently by Calvert.[10]

The artery of the spleen and all of its branches are long and slender throughout their course, and they are surrounded by a sheath of lymphatic tissue, which accumulates into the Malpighian follicles at the origin of the central artery of the lobule and continues to the ends of the arteries as the ellipsoid sheath. The central artery of the lobule gives rise to ten main branches, each of which in turn gives rise to about six hundred terminal branches. The final branches lie in the centre of the histological unit, and in a distended spleen the distance between them and the vein plexus is about 20 μ.

When the artery of the spleen is injected with fluids, *e.g.*, gelatin, an extravasation takes place as soon as the injection enters the lobule; it is most intense around the periphery of the lymph follicle, around the arteries toward their termination, and throughout the histological units or pulp; it never takes place within the lymph follicle. When the injection of the spleen is incomplete it is found that the veins are injected only at the points of extravasation. The various authors who advocate an open circulation through the spleen base their conclusions upon the above tests, while those who advocate a closed circulation have occasionally observed a direct communication between the artery and vein. It matters little which opinion is correct, for in any case an extravasation invariably takes place when the artery is injected with a fluid, showing that a similar thing may take place in the living spleen. And since this takes place in part at least, we must admit that there is constantly a stream of blood plasma passing out of the artery into the pulp, which again must flow into the vein and not into the lymphatic channels, for they are not present. When, however, the spleen is distended to its maximum by tying the splenic vein, as well as its anastomoses with the gastric, half an hour before killing the animal, a subsequent injection of the artery with an aqueous solution of Prussian blue gives specimens which are most instructive. The spleen pulp is so distended with blood that there is no further space for the Prussian blue in it and it must take the course of the least resistance. This naturally is over toward the vein for before injecting the artery of the spleen the veins were opened to relieve the tension in them. If then there is any direct connection between the artery and vein it must be injected by this method. Fig. 4467 is from a specimen made by this method. It is seen that the terminal artery suddenly widens, passes toward the vein, and then communicates with it. In every respect this confirms Thoma's description of the termination of the artery within the spleen.[11] For a long time I have been obtaining specimens from time to time, which show that there is a communication between the artery and vein, but until recently I was unable to obtain complete injections in every specimen until I invented this method; for with ordinary methods the injections may be complete in one specimen while the next specimen treated in the identical way has a diffuse injection, barely showing the terminal arteries. I finally found that these ampullæ are very marked if an œdematous or a hemorrhagic spleen is injected with aqueous Prussian blue, a fluid which precipitates very easily. I have never been able to demonstrate them with carmine gelatin as it diffuses with the greatest ease. There are then marked channels, or the ampullæ of Thoma, connecting the arteries with the veins, which can be demonstrated by certain methods. From time to time it appeared to me that the ampullæ marked artificial channels, but their constancy, their direction and their arrangement being always so characteristic, as well as the fact that they are present in uninjected specimens, are sufficient evidence against this view. The fact that

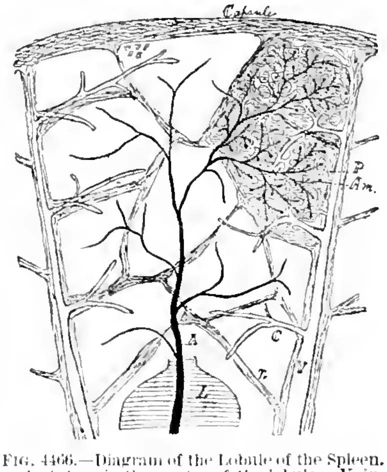

FIG. 4466.—Diagram of the Lobule of the Spleen. *A*, Artery in the centre of the lobule; *V*, interlobular vein within the interlobular trabeculæ; *Tr*, intralobular trabeculæ; *L*, Malpighian follicle; *C*, intralobular collecting vein; *P*, intralobular vein plexus which surrounds the pulp cords or histological units; *Am*, ampulla of Thoma.

they are easily injected only when the rest of the spleen is filled with fluid appears to indicate that they may be reserve channels through which the circulation can pass only when the spleen is hyperæmic, as it is during digestion.

The arterial end of the ampulla is much more easily injected than the venous end, and apparently for this reason Thoma divides the communication between the artery and the vein into two parts, the ampulla or the arterial end, and the *Zwischenstück* or the venous end. There is no sharp line of demarcation between the ampulla and the Zwischenstück, for the one passes directly over into the other. This division I find very artificial, and in describing the different portions of the ampulla I shall divide it into thirds, numbering them from the artery to the vein.

The first third of the ampulla is a marked space lined with spindle-shaped cells, which are a continuation of the endothelial cells of the artery.

In the second third the ampulla has a tendency to divide the subdivisions in such a way that some of them communicate with the divisions from neighboring ampullæ. The anastomoses of ampullæ pass along the middle of the pulp cord, and if care is not taken it may be mistaken for the vein. However, double injections with granules in the veins excludes this source of error. The last third is much more difficult to demonstrate than the first two thirds. Thoma has already emphasized this point in stating that the ampulla appears to communicate with the vein when viewed with a low power of the microscope; that with the high power, however, it is shown that the ampulla passes over and under the vein, but not into it. This description applies to what I have called the first two thirds of the ampulla. Successful injections leave no doubt whatever about the ampullæ communicating directly with the vein, as shown in Fig. 4467. To be sure, it may be asserted that the spleen pulp in this specimen was so gorged with blood that the Prussian blue injected was forced to take the direct course through the tissues into the vein. To settle this question further I made rapid injections with Prussian blue into the artery of a spleen which had been distended, but not to its maximum, by injecting chrome yellow suspended in gelatin into the vein. The gelatin passed over into the tissues and the yellow remained in the vein. The smaller quantity of blue injected into the artery extravasated as usual at numerous points and flowed into the veins in the immediate neighborhood. Where the injection was not so intense spots were found in which the blue from the artery passed directly over into the vein. In such specimens the extravasation of the blue takes place along the artery as much as it does in any portion of the ampulla, and it appears from this that the walls of the last third of the ampulla are fairly complete, otherwise the injection would have passed into the pulp spaces immediately surrounding it.

By studying numerous successful injections of the last third of the ampulla I find that its communication with the vein is not wide, but is cut up by bridges of tissue passing across its lumen before it connects with the vein. This is so extensive that in uninjected specimens it has been impossible for me to show that the ampulla communicates with the vein. That the ampulla can never be injected from the vein is an additional argument for the idea that there is an obstruction near its connection with the vein.

If the artery of the spleen is injected with gelatin in which cinnabar granules are suspended it is found that the granules are forced over into the veins only under special conditions. Ordinarily the granules pass to the origin of the ampullæ and then can be forced no farther, nor can they be forced through the walls of any of the arteries. When, however, the cinnabar is driven into the artery with a high pulsating force for a long-continued time, it is found that the granules pass beyond the ends of the arteries and the gelatin diffuses, thus causing an artificial œdema. Many of the granules enter the pulp spaces, but by all odds the greater number of them pass over into the veins. Often so many of the granules pass over into the veins that it appears as if the veins had been injected by them. The extravasation of granules into the pulp spaces is most intense around the lymph follicles, which is also true in the case of other injections. It appears as if in the neighborhood of the lymph follicles the walls of the ampullæ are most porous.

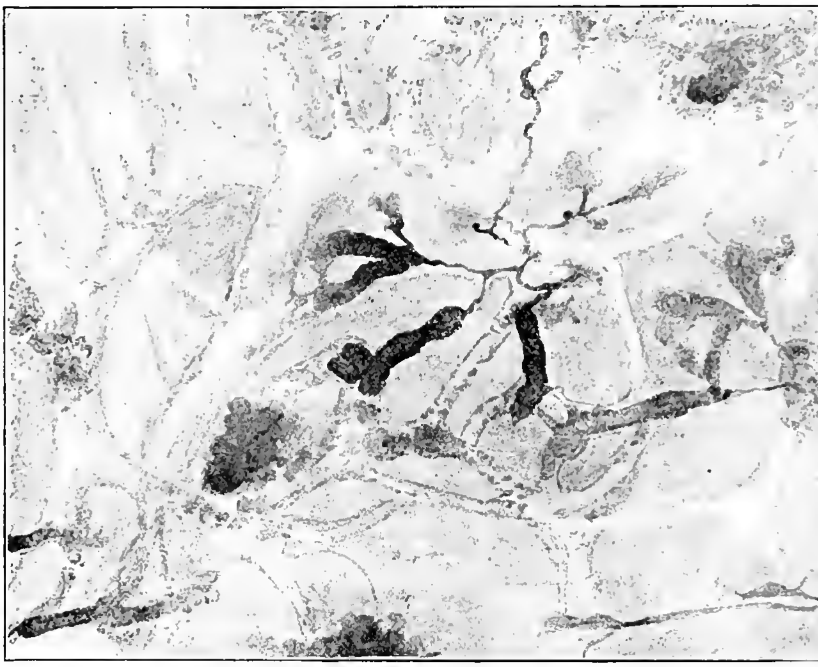

FIG. 4467.—Section of a Spleen Distended to its Maximum by Tying the Vein One Hour before Killing the Animal. The artery was then injected with aqueous Prussian blue. Enlarged 60 diameters. The ampullæ communicate with one another and also directly with the intralobular venous plexus.

In all of the specimens in which the artery had been injected with cinnabar the ampullæ are not sharply outlined. All granules which enter them are carried over into the veins at once. This result corresponds fully with natural injections made by ligating the veins. In any case there must be some mechanism which empties the ampullæ, as they are never found distended with cinnabar granules or with red blood discs.

Whether the course of the granules is from the ampullæ directly to the veins, or indirectly through the pulp is another question. Were it through the pulp we would expect to find the tissue first filled with granules or blood, as the case might be, before they entered the veins. Instead of this we find that in the natural injections the blood first fills the veins and then the pulp spaces, and when the pulp spaces are overdistended with blood, the corpuscles do not return to the veins after the pressure in them has been removed. If there were a constant circulation from the ampullæ through the tissues into the vein, the blood discs in the pulp spaces should be forced into the veins in the above experiment. Furthermore, if the muscle of the spleen is paralyzed by cutting its nerves, a great quantity of blood passes over into the pulp spaces causing a hemorrhagic infarction, which shows that the elasticity of the reticulum alone is not sufficient to keep the blood out of the pulp spaces. If all the circulation of blood were through the pulp spaces, and if the contraction of the muscle of the capsule and trabeculæ forces the corpuscles from them into the veins, then the pulp spaces should remain empty after the obstruction of the veins which produced an infarction has been removed. These experiments are considered now only to the extent in which they relate to the walls of the ampullæ. Their bearings are of such great physiological significance that they will be discussed more extensively presently.

The walls of the arteries are surrounded with a sheath of lymphatic tissue throughout its whole course. The layer of round cells is greatly reduced around the first third of the ampulla, but it often increases again at the end of it, thus aiding to separate the first third from the second. From the end of the first third of the ampulla to the vein there are no marked walls, not more than the increased number of reticulum fibrils (Fig. 4461). Injections with solutions of nitrate of silver outline the first third of the ampulla extremely well, and show that the sharp endothelial lining of the artery reaches nearly to the ampulla. Then the cells become irregular in shape and finally are represented as long spindle cells which lie upon a framework of reticulum. Throughout the second third the walls of the ampulla are still faintly marked by spindle and multipolar cells, but I have been unable to demonstrate any distinct cell walls in the last third. In sections of uninjected specimens this third appears to communicate as freely with the pulp spaces as with the veins.

The sections and injections show (1) that the walls of the ampulla become more and more porous as the vein is approached; (2) that the walls of the whole venous plexus of the lobule, especially in the distended spleen, are also very porous; and (3) that at the point of junction between the ampulla and the vein there is no marked blood-vessel wall other than a dense network of reticular fibrils.

The experiments show that if the muscle is paralyzed the blood discs enter the pulp spaces, thus causing a hemorrhagic infarction, and that under normal conditions all the tissues are bathed in plasma while the solid elements of the blood pass directly from the ampullæ into the veins.

Experiments on the Circulation through the Spleen.—The experiments here recorded were made to test what influence the contraction of the trabeculæ and capsule may have upon the circulation through the spleen. It is well known that at certain times the spleen is very hyperæmic and dilated, while at other times it is anæmic and contracted. In addition to this periodic change in volume its muscle is also constantly contracting rhythmically. Since the arteries are very long and slender and end in so many branches it is evident that the resistance in them must be very great. Their muscle walls are also so powerful that it is practically impossible to inject them completely in a contracted spleen. If artificial circulation is carried on through a spleen in which the muscle is alive and contracted, it is found that the spleen must be distended considerably before any fluid comes out of the vein. This usually takes a number of minutes after the artificial circulation is started, and from it we must conclude that the circulation through a distended spleen is much easier than through a contracted one.

I have been unable to obtain this result in the living animal with the normal circulation unbroken, for all the operations which I performed upon the veins always caused the hyperæmic spleen to contract. A number of experiments, however, gave some good data regarding the venous outflow in a spleen fairly well contracted, as usually seen in the living animal. With all the arterial anastomoses ligated the quantity of blood which flowed from the vein was usually 25 c.c. every five minutes, or about two drops per second in dogs weighing 10 kgm. When we consider the five hundred million arterial endings in the spleen we realize how very slow the circulation must be through them. In the intestine of the same animal there are not over five million arterial terminations and the blood simply rushes through the superior mesenteric vein. I have never been able to measure the quantity of blood which passes through splenic veins when the spleen is hyperæmic, but it is very free when artificial circulation is carried on through the distended organ. If the spleen is made very hyperæmic by ligating the veins in a living animal there is a great gush of blood from the vein in case it is opened; but accompanying this there is a corresponding contraction of the organ, showing that in addition to the natural circulation through the spleen the blood lodged within it is also pressed out by the contraction of its intrinsic muscles.

When a spleen, which is physiologically hyperæmic, is irritated either directly or through its nerves, it is found that the contraction which follows forces the blood contained in it through the vein and then it becomes pale. The same result is observed when an hyperæmic spleen is completely removed from the body; it gradually contracts and forces the blood contained in it through the vein. These observations indicate that when the blood is once within the venous plexus and large veins of the spleen a contraction of the muscles forces the blood out through the vein, thus aiding in the circulation through the organ, as is the case in the intestine. The presence of valves at the point where the veins leave the spleen prevents the blood when once forced out from returning to the organ again when its muscle relaxes. To test this point I made a number of experiments, measuring the pressure within the vein, after it had been tied, while the spleen is contracting. Unfortunately the activity of the muscle of the spleen varies very much in different animals, and I have been unable to control this factor. In some experiments the spleen simply continued to distend after ligating the vein without any perceptible increase of pressure in the vein. At other times the spleen responded beautifully when irritated. In one experiment the venous pressure was 15 mm. Hg. before closing the vein; after closing, it rose to 180 mm. Hg. After it had reached this height ligating the artery further irritated the spleen muscle, causing the venous pressure to rise to 190. In another animal the venous pressure in the spleen with the vein closed registered every five minutes as follows: 20, 70, 106, 60, 140, 90 mm. Hg. At no time could I observe any contraction of the organ. The maximum pressures of 106 and 140 mm. were in each case accompanied by great struggling of the animal. In another spleen the venous pressure registered constantly at 7 mm. Hg. after closing the splenic veins, and the organ was gradually becoming hyperæmic. Irritation of the nerves about the artery caused the venous pressure to rise to 20 mm., but this would soon fall again to 7 mm. All other irritants, like hot water or closing the artery, did not cause the spleen to contract nor the venous pressure to rise.

These experiments, although incomplete, show that the contraction of the spleen causes the pressure in the splenic vein to rise, and from what has been said above regarding the anatomy of the spleen this is to be expected. Therefore it is highly probable that the physiological rhythmic contraction of the spleen, acting partly upon the veins, is a great factor in the circulation through the organ.

While we can cause contraction of the muscle of the spleen, and observe its effect upon the venous blood pressure, we can also make the opposite experiment by paralyzing the muscle. Jaschkowitz[12] has shown by cutting the nerves around the splenic artery that an extreme hemorrhage into the pulp spaces follows. I have repeated Jaschkowitz's experiment a number of times and obtained his results in each case. In making the experiment I isolated the artery and vein completely with a probe and passed a double ligature around all the tissues about these vessels. After tying both ligatures I cut between them, thus excluding every possibility of an error. In certain experiments an individual nerve or the nerves around one branch of the artery were not cut, thus making the control experiment at the same time. At the end of twenty-four hours the animals were killed, and in each case there was an extensive hemorrhagic infarction of the spleen; if all the nerves had been cut the hemorrhage was throughout the whole spleen, while if certain nerve branches were not cut, the spleen tissue innervated by these branches remained unchanged. Before killing the animals, first the vein and then the artery was opened, showing that there was no obstruction in either of them due to the operation. Irritation of the spleen with hot water caused no contraction in case all the nerves had been cut, while if some nerves remained uncut, the portion of the spleen innervated by them would respond to irritants. The border line between the normal and hemorrhagic, which was very hyperæmic, would respond to irritants. This last test undoubtedly shows that within every portion of the spleen there is an overlapping of the nerves, as is the case in many other portions of the body.

Since irritation of the splenic nerves causes contraction of the spleen, and since cutting the nerves causes paralysis of the muscle of the spleen, it is probable that the results upon the circulation following these two experiments are due to the excessive or diminished activity of the muscle. On the one hand, the contraction presses blood out of the spleen, while on the other hand the removal of this force allows the blood to accumulate in the spleen. Sections of spleens made hemorrhagic by cutting the nerves show that whenever the tissues are filled with blood the veins are likewise filled, but in numerous places the veins are full and the pulp spaces empty, corresponding with the results obtained by Thoma after tying the splenic vein. It therefore seems that the pulp spaces are in all cases filled with blood through the openings in the walls of the veins. Yet I am unwilling to accept this explanation until further arguments are made to support it, but am rather inclined to the idea that the pulp is filled with blood through the openings in the walls of the ampullæ.

The reasons why I believe that the escape of blood corpuscles is through the walls of the ampullæ to produce the hemorrhagic infarction after cutting the nerves are: (1) the anatomy of the ampulla; (2) the fact that granules injected into the artery pass mostly into the veins and partly into the tissues; and (3) hemorrhagic infarction produced in other organs takes place mostly through the capillary walls.

I have shown sufficiently above the characteristics of the walls of the ampullæ. That as soon as they begin the endothelial cells of the artery become spindle-shaped and are separated, and that a distinct cell wall cannot be followed to the vein. Furthermore any fluid injected into the artery will invariably pass immediately over into the pulp, thus causing an artificial œdema. When this is complete the fluid then flows from the veins. The extent of this œdema in the spleen under normal conditions would depend upon the tone of the muscles of the trabeculæ. It does not appear that the natural elasticity of the reticulum of the pulp and of the elastic tissue of the trabeculæ and capsule are sufficient to prevent this, as shown by artificial circulation through the isolated spleen as well as by producing paralysis of the muscle in the living animal by cutting the splenic nerves.

Long-continued circulation with cinnabar granules suspended in gelatin through the isolated spleen shows that the bulk of the granules pass directly into the vein while a considerable number of them enter the pulp spaces. When such an injection is continued long enough the granules passing into the pulp will naturally accumulate, as does the blood when the nerves are cut. The few red discs which normally pass out into the tissues will probably remain there until destroyed by the various migrating cells, then to be carried into the veins by them. Sections of a spleen which has been distended with gelatin, as well as the relative number of red and white blood discs within the vein under normal conditions, suggest this. Furthermore, the veins have the largest openings in their walls nearest the lymph follicles.

Numerous experiments, made by Welch and myself, upon the blood-vessels of the intestine have shown that hemorrhagic infarction takes place only with considerable blood pressure within the arteries and capillaries. When the vein only is tied or when the venous pressure is greatly increased, with the artery closed, the expulsion of red discs through the thin capillary walls is easily understood. When, however, the artery is tied and the vein left open, as is the case when an embolus lodges in the superior mesenteric artery, the cause of the following diapedesis throughout the mucosa of the intestine is not easily understood. Many experiments have shown that it is not necrosis of the capillary walls and venous regurgitation, for after the whole intestine has been deprived of its circulation for twenty-four hours, re-establishing it does not produce an infarction nor hasten it. An infarction of the intestine takes place after ligature of the superior mesenteric artery just as rapidly with the mesenteric vein cut open as it does under the normal portal pressure of 7 mm. Hg.

All the usual explanations of hemorrhagic infarction, as printed in the pathologies, are incorrect when applied to the intestine. The superior mesenteric artery with its branches suspended in a membrane is eminently adapted to experiments to test this question. The pressure in the vessels can be increased and gradually modified in different portions of the intestine, and it is found that when the arterial pressure is reduced to one-third its normal with the vein either intact or cut open, an infarction invariably follows. Cutting off all the anastomoses and partly closing the main artery with clamps until the pressure in the distal end is about 40 mm. Hg. produce an infarction. It does not appear, however, that the infarction is due to the reduction of the arterial pressure to 40 mm. Hg., but rather to the lack of a pulse wave, which is almost completely cut off at this pressure.

The experiments of von Frey[13] with artificial circulation through isolated organs have shown that the lack of a pulse wave in the artery always causes them to clog with red blood discs, while the presence of a pulse prevents this by not permitting the red discs to stick together, for it constantly tears them apart. When they stick together they gradually block the capillaries, and then the lateral (lymphatic) circulation drags with it the straggling red discs, thus choking up the tissue to produce hemorrhagic infarction. The result obtained by von Frey in an isolated organ in which artificial circulation is carried on without a pulse wave has also been found in the living intestine when the artery is closed sufficiently to break the pulse in its distal end. The infarction produced by long-continued circulation through the artery under constant pressure is due to a condition which blocks the capillaries, but still leaves the blood within them under considerable pressure. The important factor is stagnation, due to the absence of a pulse in case the artery is tied, while if the stagnation is produced by ligating the vein the presence of a pulse only hastens the infarction. In one case there is a pulse, in the other there is not, while in both the result is the same.

I have given then a brief summary of some unpublished work in order to discuss the infarction within the spleen following division of the nerves. The great sectional area of the ampullæ as well as the great number of them (at least five hundred million), together with the long, slender arteries, must cut down the pulse in the ampullæ enormously. Hence with the normal circulation through the spleen we have present most favorable conditions for diapedesis. Not only is the circulation slow and the pulse wave insignificant, but the walls of the ampullæ (capillaries) are incomplete. So, therefore, without the rhythmic contraction of the spleen to aid the circulation a hemorrhagic infarction takes place. The quantity of discs which normally passes from the ampulla into the pulp spaces is increased while a share of the blood still passes over into the veins, just as is the case in the intestine when infarction is taking place after ligature of the superior mesenteric artery. With the spleen pulse present, however, the constant pressure upon the pulp produced by the elasticity of the connective tissues and the tone of the muscle are sufficient to drive the blood discs through the channels of the least resistance, as is the case when a distended spleen is injected (Fig. 4467).

The balance between the arterial pulse, ampullæ, and spleen pulse is so delicate that when it is proper the blood discs will "creep single file" over into the vein, while the least overthrow of it will drag an increased number of corpuscles with the normal flow of plasma over into the pulp spaces to make a pathological condition—hemorrhagic infarction.

The Nerves of the Spleen.—The nerves of the spleen accompany the artery and are composed mostly of non-medullated fibres.[14] It is quite easy to separate them by the ordinary methods of dissection and to follow them far into the spleen. With the aid of the dissecting microscope Kölliker was able to follow them to the Malpighian corpuscles, while with the aid of Golgi's method Retzius followed them to their terminations in the spleen substance. Rich plexuses of fine nerves surround all of the arteries which supply the muscle fibres of the media. A second group of nerves go to the muscle fibres of the trabeculæ. This distribution explains the physiological experiments: (1) Irritation of the splenic artery causes contraction of the whole spleen; and (2) cutting these nerves causes paralysis of these muscles followed by hyperæmia and hemorrhagic infarction. According to Kölliker the presence of some medullated nerve fibres in the spleen accounts for the pain felt in this organ at times. It is impossible to determine with certainty by the method of Golgi whether or not the nerve fibres leave the trabeculæ and walls of the arteries to enter the substance of the pulp, for the precipitation of the silver often outlines the reticulum fibrils also.

The Spleen Pulp.—The red substance of the spleen, the true spleen pulp, is arranged in bands which anastomose in all planes, inasmuch as it fills all of the space between the capillary veins, similar to the arrangement between the cells and capillaries of the liver. The framework of the pulp is composed of reticulum, the nature of which has been already discussed. There appear to be some elastic fibres encircling the veins, and also within the Malpighian corpuscles, as is the case in all lymph glands.

The small mononuclear lymphocytes, which form the main mass of the Malpighian corpuscles, are found scattered throughout the pulp substance, except along the arteries, where they form a kind of a sheath to the outside of the muscle wall.

The large leucocytes are in general more numerous, and they are also numerous in the centres of Malpighian corpuscles. They are partly unicellular and partly multicellular, and in addition there are granular forms, some of which are intensely stained with eosin (eosinophile cells). The large brown cells (phagocytes) which contain much blood pigment must also be recorded with the leucocytes. They are found scattered in an irregular fashion throughout the pulp of the spleen. The contents of the phagocytes are also found free in the pulp. Red blood corpuscles lie scattered singly and in groups within the meshes of the reticulum of the pulp. As a rule giant cells and nucleated red blood cells are not found in the pulp of the adult spleen, but there are cells present which cannot for the present be arranged with certainty in the series of leucocytes or the series of erythrocytes. These cells are pretty large and have a very fine granular protoplasm which stains more intensely with eosin than does the protoplasm of leucocytes. The nucleus is round or oval, seldom constricted, and never lobulated, and often contains marked nucleoli. In preparations made from tissue hardened in sublimate the nuclei of these cells resemble those of the reticulum, but unlike them lie free within its meshes. Large giant cells, similar to those in bone marrow and in the liver of the embryo, are also found. Their nuclei are large and lobulated, or are pressed together into a heap. In order to differentiate them from the giant cells with many nuclei they are called megacarocytes. It has been found by Kölliker that they are present in the spleen of embryos and of young animals and occasionally in the spleen of the adult—the mouse for instance. There are also constantly present in the spleen of young animals very small granules which can be found in very large numbers in teased preparations. They resemble very much blood platelets, but are more resistant, for they can be preserved for a very long time in salt solution. They also have a tendency to take on irregular shapes and to form clumps.

The question is naturally asked, Is the spleen a blood-producing organ? The more the question is studied the less probable it becomes that the spleen plays any rôle in the production of blood. The coarse counts of the number of white and red cells in the artery and in the vein or the increased number of white cells in leucocythæmia are of little value when examined critically and experimentally. According to Ehrlich,[15] to whom we owe much regarding our knowledge of the blood, the leucocytes are greatly increased in number after extirpation of the spleen, which is accompanied with a marked hypertrophy of the lymph glands of the body. Extensive experiments were carried on in Ehrlich's laboratory by Kurloff, from which the following conclusion is drawn: That the spleen of the guinea-pig plays an insignificant rôle in the formation of the white blood corpuscles.

It is also very apparent that the relation of the spleen to the formation of red blood corpuscles varies much in different animals and at different periods in the development of the same animal. In lower vertebrates the spleen is a great factor in the production of red blood corpuscles. In mammals, however, it generally plays no rôle whatever in their production. Nucleated red corpuscles are found in relatively large numbers in the mouse's spleen; in smaller number in the spleen of the rabbit; in that of the dog during the anæmia following hemorrhage; and in the human spleen only during leukæmia.

It appears as if the spleen of higher animals is a place for the destruction of blood corpuscles, especially those which have been partly destroyed. So Ponfick has found that in the destruction of red corpuscles the spleen takes up a part of the "shadows" of the red cells and produces a spleen tumor, and Ehrlich has found that the enlarged spleen in many infectious diseases is produced by the products of disintegrated leucocytes which are there accumulated. *Franklin P. Mall.*

SPLEEN, DISEASES OF THE.—General Considerations.—Developmentally, the spleen belongs to the mesoblastic tissues. It is derived from the mesogastrium, and in its origin is closely related to the pancreas, but has none of the hypoblastic elements which enter into the formation of the latter. It first appears during the second month of fœtal life and develops slowly, so that it is not complete until nearly the end of that period.

Structurally, and, as will be seen later, to some extent physiologically, the spleen is closely allied to the lymphatic nodes or glands. The framework of the spleen is connective tissue, which is massed especially in the capsule, giving the general form of the organ; in the trabeculæ, which are processes running from the capsule into the substance of the viscus, and dividing it into smaller parts; and, finally, in a fine meshwork which fills these parts and divides them into minute spaces, the so-called pulp spaces of the organ. Connected with this fine connective-tissue meshwork are many stellate branching cells. The walls of the pulp spaces are lined with small or large endothelial cells. In the meshes of the connective tissue framework, that is in the pulp spaces, are great numbers of small round cells or lymphocytes. The blood supply is the splenic artery, whose main divisions run along the trabeculæ of the organ, then, subdividing into smaller branches, pass into the so-called pulp. Upon the walls of, or around, the smaller arterioles are clustered here and there masses of lymphoid cells which constitute the Malpighian bodies of the spleen. These bodies correspond in a general way with the lymph follicles of the lymph nodes, and the pulp spaces of the spleen correspond to the lymph sinuses of the nodes. The pulp spaces constitute the beginnings of the venous radicles of the organ, which gather up the blood to pass it on to the splenic vein. The nerves of the organ are derived from the cœliac plexus and the right vagus, and to some extent they accompany the branches of the splenic artery.

The size and weight of the spleen vary considerably even in conditions of health. During the first year of life it weighs from 15 to 20 gm., in adult life from 140 to 200 gm.

Anatomically the spleen stands in close contact with the stomach, and the blood supplies of the two are closely related. In some of its functions also it is associated with the stomach and liver. It is therefore not uncommon to find it classified as belonging to the digestive system.

From what has already been said with regard to the structure of the spleen, its close kinship to the lymphatic apparatus, and its anatomical relations to the digestive organs, we may expect that it will but rarely become the seat of primary disease, but that it will participate largely in systemic disorders and in local disturbances, especially those involving obstruction to the circulation in the portal system. In fact, apart from the extremely rare cases of primary malignant disease of the spleen, there are but two affections in which it appears to play the primary or chief rôle. These are the splenic form of leukæmia, and the disease or group of diseases which has lately been designated as splenic anæmia. It is, however, still an open question whether in either of these the rôle of the spleen is primary. We can only say that in some at least of the cases included in these categories such seems to be the case.

Abnormalities.—Absence of the spleen is met with in some cases of acephalic monsters and in premature fœtuses with imperfect development of the skull. Litten records two cases in which no spleen could be found in bodies otherwise perfect, but as one of them dates back to the sixteenth century, the condition must be an exceedingly rare one. Supernumerary spleens, on the other hand, are extremely common, being found in about one body in four. In number they vary from one or two up to forty. They are found near the hilus of the spleen, in the gastrosplenic omentum, in the great omentum, and even in the pancreas. In size they are usually small, 0.5 to 1 cm. in diameter, but they may reach considerable proportions. The absence of the usual symptoms after splenectomy in some instances has been explained on the basis of the presence of supernumerary organs.

A recent study by Parsons shows that there is great variation as to the number and arrangement of the notches and fissures of the spleen. On the anterior border he found that some spleens had no notch, while, when they were present, they varied from one to eight in number. About one-third of the specimens examined showed notches on the posterior border and one-fifth had fissures on the parietal surface.

Abnormal Placement.—Congenital abnormalities in the position of the spleen are observed in rare instances. The most interesting of these is the placement of the spleen in the right hypochondrium in cases of transposition of the viscera. The spleen may be found outside the usual limits of the abdomen in cases of large umbilical hernia, and has even been found in the left thorax in connection with defect of the diaphragm. Von Löwenwald records a case in which the spleen was found attached upon the spinal column.

Movable or Wandering Spleen.—The spleen is normally in position in the left hypochondrium, touching the ninth, tenth, and eleventh ribs, its long axis almost in the line of direction of the tenth rib, its upper and posterior end being about 2 cm. from the vertebral column and its anterior and lower extremity being about 3 cm. from the margin of the ribs in front. It is suspended by several folds of peritoneum, one passing from the greater curvature of the stomach to the hilus, another from the upper end of the spleen to the diaphragm, and a third from the diaphragm to the splenic flexure of the colon. The last of these suspends the spleen as in a sling and is its chief support.

The normal spleen enjoys a certain amount of mobility and may be depressed from above by effusions in the left thorax, emphysema, etc., or may be displaced upward by fluid in the abdomen or by distention of the colon with gas or fæces. In the condition of movable or wandering spleen, however, all the suspensory ligaments are lengthened or relaxed and the spleen is displaced downward into either the abdomen or the pelvis.

Etiology.—The condition may be one of the features of a general splanchnoptosis produced by trauma, such as sudden falls, or by lifting heavy weights, but is most commonly a result of the persistent dragging of an enlarged and heavy spleen upon its attachments, especially likely to be seen in such affections as malaria, leukæmia, or splenic anæmia.

Morbid Anatomy.—The spleen itself may present any one of the various types of chronic enlargement, or in rare instances it may be normal. The ligaments are all stretched, and with them the splenic artery and vein. The latter may be dilated to enormous size. The tail of the pancreas and the greater curvature of the stomach are dragged down with the spleen and deformity or dilatation of the latter organ may result. The pedicle of the spleen may become twisted upon itself with secondary atrophy of the organ, or even, in case of complete obstruction of the circulation, with gangrene.

Symptoms.—There may be no symptoms whatever, and the displaced viscus may be discovered by accident. There may be pain due to the weight and pressure of the spleen in an abnormal location, or dragging pain due to the stretching of the ligaments. In many instances the patients are neurasthenics and present characteristic symptoms of that disorder.

Diagnosis.—This rests upon two points: First, the recognition of a solid tumor in the abdomen or pelvis as the spleen; and, secondly, the demonstration of the absence of the spleen from its normal situation. The first is usually easy, if the possibility be present to the mind, the smooth, hard, rounded external surface, the sharp anterior border with its notch or notches and the rounded ends being characteristic. The second point depends upon the absence of splenic dulness in the left hypochondrium. Litten suggests the observation of the colon when distended with fluid, and then again evacuated as an aid to diagnosis, but this is not usually required

Treatment.—An abdominal bandage or binder may be sufficient to retain the spleen in its normal place; if not, operative measures are called for. A number of instances are on record of successful suturing of the spleen in its proper bed, but splenectomy seems to be the preferable operation.

Acute Hyperplasia of the Spleen; Acute Splenic Tumor; Acute Splenitis.—*Etiology.*—In all the acute infectious diseases an acute enlargement of the spleen may be met with, especially in malaria, typhoid, pyæmia, pneumonia, and the exanthemata. The exact significance of this change in the spleen has not yet been clearly determined. That in all cases of bacterial invasion of the blood the spleen plays the part of a filter is well known, and also that even in cases in which the bacteria are but rarely found in the blood, such as typhoid fever, they nevertheless abound in the spleen. We also know that in these cases there is always a more or less active hæmolysis going on in the spleen. So much is clear. The interpretation of these facts and many kindred ones developed by experimentation has furnished a difficult problem. Metschnikoff and his followers regard the spleen as a centre for the manufacture of phagocytes, and therefore as an active agent in the protection of the body against microbic invasions. Extensive experiments have been conducted upon normal and splenectomized animals to test the part played by the spleen in this relation. The results of such investigations as those of Kanthack, Tizzoni and Cattani, Blumreich and Jacoby, have been entirely indecisive of this question. Jawein has recently published the results of a long series of experiments, from which he concludes that the essential function of the spleen is one of hæmolysis, that its enlargement in the acute infectious diseases is in exact proportion to the extent of the hæmolysis occurring in each particular case, and that in the cases in which no hæmolysis occurs there is no splenic enlargement. After full consideration of all these data Rolleston concludes that the spleen in fact is and behaves like a lymphatic gland broken up and embedded in erectile tissue. The Malpighian bodies and adenoid tissue play much the same part that lymphatic glands do elsewhere, while the open, loose, vascular tissue of the organ serves rather as a filter in which various bodies are deposited by the blood, perhaps to remain, perhaps to undergo subsequent changes.

Morbid Anatomy or Pathology.—The spleen is regularly swollen, the capsule stretched, and in many instances it shows patches of thickening. The organ is usually soft, but may be even firmer than normal. On section the pulp is usually found to be deep red and soft, or even diffluent. In some instances the Malpighian bodies show more prominently than usual and the cut section at first sight looks as though studded with miliary tubercles; in other cases these bodies are quite obscured by the swelling and congestion of the pulp. Microscopical examination shows the enlargement to be due to congestion and swelling of the pulp or the glomeruli or both, together with some increase in cells. The chief increase is in cells resembling those of the normal splenic pulp, but multiplication of the living cells of the pulp spaces may be observed, as well as large multinucleated or ovoid and polyhedral cells whose origin is not clear. In some instances small areas of softening, looking like small abscesses, are met with. These are the so-called focal necroses seen also in the liver, kidneys, and lymph nodes in various infectious disorders.

Symptoms.—Apart from the change in size this affection is usually devoid of symptoms. In some instances, however, it is attended with a sense of weight, or distinct pain, in the left hypochondrium, and the organ itself may be tender to pressure. The enlargement of the spleen is detected by palpation, as a rule; but in some instances the spleen may be enlarged and yet not be palpable. In such cases the results of percussion must be relied upon, but they are always very uncertain and often deceptive.

Treatment.—From what has been already said it is apparent that acute hyperplasia of the spleen is in itself a symptom of many disorders, not a primary disease. The treatment of the primary affection is all that is required.

Chronic Hyperplasia of the Spleen.—*Etiology.*—Chronic hyperplasia of the spleen, like the acute affection, is not a primary disorder but a symptom seen in a variety of affections,—congenital or acquired syphilis, rickets, prolonged fevers especially typhoid,—and most of all, in chronic malaria and in leukæmia or pseudoleukæmia. The enlargement observed in the affection known as splenic anæmia will be considered elsewhere.

Pathology.—As a rule the enlargement of the spleen in this condition is marked, amounting in some instances to an increase of ten or fifteen times the weight of the normal organ. The spleen may, however, be but little larger than normal. The enlargement is usually symmetrical, so that the organ preserves in general the normal outline, and the notches and fissures can be seen or felt. The organ is usually harder than normal, and the change of consistence may be very marked. The capsule may show some patches of thickening, or in many instances it is generally thickened and a chronic perisplenitis with adhesions to the surrounding parts, the diaphragm, abdominal wall, intestines, stomach, etc., is a feature of the condition. The appearances upon section vary greatly. As in acute hyperplasia, the Malpighian bodies may be lost in the swelling of the pulp, but more often they are notably enlarged and prominent. The color may be uniformly dark, deep brown, or even black, but is more frequently mottled, red, and gray. The trabeculæ may be thickened to such an extent that they are readily visible as bands of fibrous tissue running in from the capsule of the organ and interlacing in a complicated network. Pigment may be collected in such masses as to be visible.

The microscopical picture varies even more than the gross. The enlargement may be due to uniform hypertrophy of both the pulp and the reticular tissue, but in most cases the increase in fibrous tissue is the more striking feature of these cases. The trabeculæ may show extreme hypertrophy, and even the meshwork of the pulp may be greatly thickened. The glomeruli may in some cases be enlarged, while in others they are almost obliterated by the hyperplasia of the pulp cells and the connective tissue. The endothelial cells of the pulp spaces may show increase both in size and in number. Pigment is often found in the cells, either of pulp or glomeruli, and even in the connective-tissue reticulum. This pigment regularly gives the reaction for hæmosiderin, and is, therefore, probably a derivative of the hæmoglobin of the blood.

Symptoms.—The symptoms of chronic hyperplasia of the spleen are those of enlargement of the organ, or are disturbances secondary thereto.

A sense of weight or oppression in the left hypochondrium is most common; this rarely amounts to positive pain. By pressure upon the stomach nausea or vomiting may be induced, and in some instances vomiting of blood in considerable quantities occurs. Any of the abdominal viscera may be disturbed in function by the pressure of an enlarged spleen, and at least one case is on record in which the pressure upon the uterus resulted in hemorrhages, which were attributed to fibroid tumor of that viscus. The enlargement of the spleen may cause it to fill the left hypochondrium, or the whole left half of the abdomen, or even to pass over into the right half and occupy the right iliac fossa as well. As has been already noted, the enlargement is regularly symmetrical, the spleen maintaining its accustomed shape, the anterior edge being sharp and notched and the lower end rounded, so that it is easy to recognize the tumor as the spleen.

Treatment.—As with the acute enlargement, treatment must usually be directed to the underlying complaint—syphilis, rickets, malaria, or the blood diseases. By such means the enlargement may be reduced to some extent; but if true fibrous hyperplasia or hypertrophy has taken place, the organ cannot return to a normal size. Usually the improvement produced by medicinal treatment is slight. An abdominal belt, properly fitted, will sometimes relieve distress of an enlarged spleen by supporting it.

In the more serious cases splenectomy may be required, but it is astonishing how little disturbance patients may have from a spleen large enough to fill the whole left half of the abdomen, without any treatment.

Rupture of the Spleen.—*Etiology.*—Rupture of the spleen is a rare occurrence. It may occur in a normal organ, but is relatively much more frequent in the enlarged spleen of malaria, typhoid, or the blood diseases. In the case of a normal spleen considerable violence to the abdomen is required to rupture the organ. It has occurred in cases of severe falls or blows upon the abdomen or of crushing of the body by great weight, such as the passage of a vehicle over it. In the case of an organ already enlarged by disease, rupture may occur spontaneously or as the result of slight violence. The explanation of this fact is not difficult in view of the pathological changes. Rupture seems to be especially common in malarial spleens, and for this reason is much more frequently observed in the tropics than in the temperate zones. Playfair is said to have seen twenty cases of rupture of the spleen during two and a half years in the East Indies. In one case within the writer's knowledge the enlarged spleen of a primary splenomegaly (splenic anæmia) was ruptured by a slight fall upon the abdomen.

Pathology.—The spleen may be torn in various directions. There seems to be no rule as to the location or extent of the tears which are often multiple. Usually the capsule as well as the substance of the organ itself is torn, and the escaping blood is poured into the abdomen. The tear may be in the pulp alone, the capsule remaining intact, and the hemorrhage being into the organ itself. In case of extensive adhesions of the spleen to the neighboring viscera and parietes, the hemorrhage may be encapsulated and so prevented from entering the peritoneal cavity. Litten says that when the spleen is adherent to the stomach or intestines, rupture may occur in such a way that the blood is poured into one or both of these parts. Rupture of the spleen is frequently associated with rupture of other viscera, most often the liver.

Symptoms.—These are essentially those of any abdominal injury associated with internal hemorrhage. There is usually severe pain referred to the splenic region, then the symptoms of profuse hemorrhage—pallor, rapid and feeble pulse, air-hunger, faintness or unconsciousness, possibly vomiting, and in some instances convulsions. The diagnosis is not likely to be made until the abdomen is opened, unless the presence of an enlarged spleen has been previously known and the location or nature of the operative violence be such as to suggest the result.

Treatment.—The only treatment must be laparotomy with suture or packing of the wound in the organ, or splenectomy. In a case recently reported by Eisendrath, attempts to suture a rupture of the spleen failed because the sutures would not hold in the softened substance of the organ and splenectomy had to be performed. The accident is generally fatal, but a few instances of successful operation are on record.

Infarcts of the Spleen.—Infarction of the spleen may arise either by the plugging of a splenic artery by a thrombus derived from some other part of the body, or by a local thrombosis. The thrombi which are carried to the spleen by the circulation have their origin in almost all cases in an endocarditis affecting the left side of the heart and resulting in the formation of thrombi upon the diseased valves. In some instances atheroma of the aorta may be the underlying process. Litten mentions the possibility of air or fat emboli, derived in one case from the opening of a vein and in the other from a broken bone, passing the capillaries of the lung and ultimately lodging in the spleen; but such occurrences, though possible, must be rare indeed.

As a result of an endarteritis of a branch of a splenic artery or vein, thrombi may form in the spleen itself, and either block the vessel at their point of formation or be carried farther to act as emboli in some of the smaller branches of the artery.

Pathology.—As the result of the occlusion of a branch of the splenic artery we have the circulation cut off from the area supplied by the artery in question. The resulting infarct usually appears as a wedge-shaped area in the periphery of the spleen, the base often being on the surface of the organ, paler in color than normal, and surrounded by a deeper zone of hemorrhage. The paler color is due to the death of the cells of the infarcted area, which undergoes the process of degeneration commonly termed coagulation necrosis, and becomes the so-called white infarct. Later, the degenerated cells are absorbed or replaced by connective tissue, and only a scar is left to mark the site of the infarct.

It was formerly supposed that the whole infarcted area immediately after the arrest of the circulation became charged with blood by an inflow from the veins, and that this blood was later absorbed to give rise to the appearances of the white infarct, but Litten has proved this not to be the case.

The deep red granular infarctions in which the tissue is found infiltrated with red cells as in an apoplexy Litten finds to be produced most often by a thrombosis in one of the branches of the splenic vein. They, therefore, do not represent a stage in the life of the ordinary infarct, but a condition due to a somewhat different process. In either case the terminal condition remains the same.

The most important question from the clinical standpoint with respect to these infarcts is whether they are septic or aseptic. If aseptic, the process follows the course indicated above. If septic, in which case they have developed usually in the course of a pyæmia or a malignant endocarditis, the infarct undergoes suppuration and an abscess of the spleen results.

With either of these two forms there is usually associated more or less perisplenitis, the greater development of this feature being, of course, seen in the suppurative cases.

Symptoms.—Localized pain, sometimes quite sharp at the time of the lodgment of the thrombus, swelling of the spleen, and in some instances a localized friction rub to be heard over the spleen are the only symptoms of the condition.

Treatment.—There is no direct treatment of the condition, and, as a rule, none is required. The cases of suppuration will be considered under abscess.

Abscess of the Spleen.—The chief cause of abscess of the spleen, as indicated in the last section, is the lodgment of an infected thrombus, derived most often from an ulcerative endocarditis or from some pyæmic focus. Abscess of the spleen may, however, arise from the extension of a suppurative inflammation from some neighboring organ or from the perforation of a gastric ulcer. It is also met with, probably from the formation of infected thrombi, in cases of typhoid, typhus, and, most especially, recurrent or relapsing fever. Abscess of the spleen is also said to have developed in malarial fever; but if so, it must have been due to a secondary infection. Some cases of abscess have been attributed to injury, and in other cases no definite cause of the abscess formation could be disclosed.

Pathology.—The majority of the abscesses of the spleen are small. If multiple, they are scattered through the organ and the intervening tissue is but little changed. Larger abscesses may, however, form, and in some instances the organ is reduced to a sac of pus. Such an abscess has been known to rupture into the stomach, the colon, the peritoneal cavity, or through the diaphragm into the pleura; or, if the lung is adherent, even into the lung itself.

Symptoms.—Many of the smaller abscesses of the spleen, especially if deeply placed, run their course without definite symptoms. With the larger abscesses, particularly those on the surface, there may be pain and tenderness in the region of the spleen, enlargement of the organ, and the irregular or intermittent fever of septic conditions. If the abscess be very large, it is possible that fluctuation may be obtained. In doubtful cases exploratory puncture may be required, but it should be resorted to only in extreme cases. If the abscess rupture, symptoms will depend upon the course which the pus takes, that is, whether it enters the peritoneum or discharges into the stomach, colon, pleura, or lung.

Treatment.—Naturally the treatment of this condition is purely surgical. In rare instances repeated aspiration has been successful. In the majority of cases incision and drainage are required. In some few cases splenectomy has been performed for this condition.

Splenic Anæmia.—Clinical interest in affections of the spleen at present centres in the question whether there is a definite symptom-group which can be denoted by the title splenic anæmia. After a thorough consideration of all the data obtainable Osler concludes that from among the conditions with which anæmia and enlarged spleen are associated a well-defined disease may be separated and may well be designated as chronic splenic anæmia. Various other names—splenic pseudoleukæmia, splenic lymphadenoma, splenic cachexia, primitive splenomegaly, and Banti's disease—have been proposed for the disease, but for many reasons the simplest designation seems the best. The description which follows is taken from Osler's recent review of the subject.

Incidence.—The affection is a relatively rare one. Rolleston records thirty-seven cases. Osler by inquiry among the members of the American Association of Physicians secured the details of twenty-six cases which could be grouped under this title, and has reported fifteen cases which he himself has observed. A few other cases which possibly belong in this category have been reported by Harris and Herzog, Brill, Field, and the writer.

Etiology.—In this relation the striking thing is that no adequate explanation of the affection can be had. There is no malaria, no syphilis, no tuberculosis, no leukæmia, in short, no apparent cause for the splenic enlargement. C. Wilson has reported a family in which in three generations six members had enlarged spleen. Collier and the writer have each reported two cases in sisters, and Brill three cases in one family. In none of the other reported cases is there any family history.

Symptomatology.—The symptoms of the affection may be briefly summarized as a remarkably chronic and often enormous enlargement of the spleen, associated with more or less marked anæmia, frequently accompanied by hæmatemesis and pigmentation of the skin, and in a few cases showing jaundice or ascites at a late stage. The splenic enlargement may exist for five, ten, even twenty-five years. The size of the spleen varies greatly, but in many instances the spleen is huge. In one of the writer's cases a girl, weighing seventy-two pounds, had a spleen weighing twelve and a half pounds. With this enormous enlargement the spleen retains its general shape, the edge remains distinct, and the notches in the anterior margin can be readily felt. Even with very large spleens the patients, as a rule, have no great pain, but complain only of a sense of weight and pressure or occasional dragging in the left side. As the organ enlarges, it emerges from beneath the left costal arch, gradually fills the left hypochondrium, then extends downward, filling the whole left half of the abdomen, and finally may pass the middle line and fill the right iliac fossa.

The anæmia which accompanies the condition is usually of a moderate grade. Of Osler's cases the average count of the red cells was 3,425,000 per cubic millimetre, the average hæmoglobin estimation forty-seven per cent. The hæmoglobin is relatively lower than the count of the red cells. The leucocytes occasionally show an increase, but are generally below normal. The differential count of the leucocytes shows nothing characteristic.

The pigmentation of the skin occurs in most of the cases, especially those of long standing. It is a general diffuse bronzing, especially upon the exposed parts of the body, very closely resembling that seen in Addison's disease.

In many of the cases the liver is notably enlarged, but without definite disturbance of its functions; in other cases the enlargement is associated with signs of obstruction and the cases suggest cirrhosis of the liver with secondary enlargement of the spleen. Ascites and jaundice, when they do occur, are terminal events in the development of the disease.

Pathology.—In this regard two quite distinct conditions have been observed. In one there is a chronic hyperplasia of the spleen with increase of connective tissue, atrophy of the pulp, and degeneration of the Malpighian bodies. In the other group, which has usually been described under the title of primary splenomegaly, the spleen is enormously enlarged, the fibrous hyperplasia is excessive, but in addition there are irregular spaces, apparently the enlarged and deformed spaces of the splenic pulp, filled more or less completely with very large endothelial cells, having clear protoplasm and two or more nuclei, with occasional giant cells. In the original description of Gaucher the condition was termed a primary epithelioma. The writer, after careful study of many sections from his case, concluded that the condition could not be regarded as a new growth, but was an unusual form of hyperplasia of the organ. In this view he has been supported by Harris and Herzog, although these observers do not agree in the view that the endothelial cells, which form so striking a feature of the picture, may later undergo transformation into fibrous tissue. A similar structure has been observed by Picou and Ramond, Collier, Harris and Herzog, and Banta. A remarkable feature of the writer's case was the marked pigmentation found in the spleen, retroperitoneal lymph nodes, and the liver. The lymph nodes also showed changes analogous to those in the spleen, and in the intralobular connective tissue of the liver there were groups of cells closely resembling the large endothelial cells of the spleen. As a rule the changes observed in the liver are those of a simple cirrhosis. The enlargement of this organ may be marked, but is not nearly so striking as that of the spleen.

Moderate enlargement of both external and internal lymph nodes is found in some of the cases, but this enlargement is not comparable to that of leukæmia or pseudoleukæmia.

Treatment.—The only treatment so far found effective in these cases is the removal of the spleen. Sippy tabulated seven splenectomies for this condition, to which Harris and Herzog have added twelve. Out of the total of nineteen, fourteen recovered and five died. In the majority, at least, of the recoveries the condition has been completely relieved by the splenectomy. Osler regards recurrent hæmatemesis as the most important indication for operation.

Tumors of the Spleen.—Although the spleen is frequently involved secondarily in cancer and sarcoma, primary tumors of the spleen of any form are exceedingly rare. Both solid and cystic tumors have, however, been met with. Among the cystic tumors Litten distinguishes three groups: (1) Uni- or multilocular cysts of non-parasitic origin, including serous, blood, and lymph cysts; (2) echinococcus cysts; (3) dermoid and atheromatous cysts. These are very rare. Among 235 cases of echinococcus of the abdominal organs Finsen found the spleen the seat of the parasite in only 2, and Neisser in 900 cases of echinococcus collected from literature found 28 cases of echinococcus of the spleen. The only peculiarity of these cystic tumors is the sense of fluctuation which may be obtained upon palpation. Naturally this can be had only when the cyst has reached a considerable size. In the case of echinococcus it is claimed by some that a peculiar hydatid crepitation may be obtained upon palpation, but so great differences of opinion as to its occurrence exist, even among those who have had opportunity to study these cases, that one must doubt the value of the phenomenon in diagnosis.

Fibroma, cavernous angioma, and lymphangioma of the spleen have all been observed, but are all exceedingly rare. Carcinoma, so frequent secondarily in the spleen, is almost unknown as a primary growth. Litten says that there are ten primary cases recorded in literature.

Primary sarcoma is also very rare, secondary sarcoma of the spleen not very uncommon. A number of cases of removal of sarcomata of the spleen are on record.

The symptoms and diagnosis of these various tumors present no unusual features by reason of their occurrence in the spleen.

The only treatment must be the removal of the organ.

With the recent advances of surgery removal of the spleen has become much more frequent, and has been attended with much greater success than was formerly had. For the details of the operation and its results one may refer to the elaborate articles of Jonnesco, Bessel Hagen, Warbasse, Bolton, and Warren. From the standpoint of medicine the interest of splenectomy lies in the effects produced upon the organism by the operation, and the light which is thereby thrown upon the function or lack of function of the spleen. (*Cf.* also the following article.)

Effects of the Splenectomy in Animals.—Ewing briefly summarizes the results of the work of several observers as follows: Splenectomy in animals is followed by moderate reduction in red cells lasting for from one to twelve months, by relatively greater loss of hæmoglobin more slowly restored, and in some cases by the appearance, during the first year, of megalocytes. Leucocytosis follows the operation, but its extent and duration are very variable. A polynuclear leucocytosis is observed during the first days or weeks, followed by relative or absolute lymphocytosis during the first year, while during the second year distinct eosinophilia may be observed.

With these changes in the blood are associated marked cellular hyperplasia of the marrow, approaching at times that of leukæmia, and often also affecting the lymph nodes. In the swollen nodes an excessive number of nucleated red cells have been found by Winogradoff, Tizzoni, Gibson, Komloff, and Grünberg.

Effects of Splenectomy in Man.—Ewing also gives a résumé of this subject. In comparatively healthy subjects splenectomy has often been performed without affecting the blood more than does any other laparotomy. In many graver cases the loss of blood and the shock of operation give rise to a considerable grade of secondary anæmia. The red cells in favorable cases are restored in from one to three months, but in less favorable cases there may be more persistent anæmia. The restoration of hæmoglobin seems to fall behind the improvement in cells rather more than in most secondary anæmias. The operation is usually followed by considerable polynuclear leucocytosis (15,000 to 50,000) which commonly lasts from two to six weeks, but may continue for months, in which case the polynuclear cells may be largely replaced by lymphocytes. Eosinophilia has been observed in a few cases in the second and third years.

In traumatic cases suffering from large hemorrhages splenectomy, especially when complicated by infection, may lead to very profound anæmia, marked by extreme loss of red cells, the presence of very many large, pale, sometimes polychromatic, and dissolving red cells, nucleated red cells, and to a high grade of leucocytosis. Among the leucocytes there may be a considerable proportion of large, pale mononuclear cells and myelocytes, so that the blood resembles that of acute leukæmia. This condition, however, is transitory and the blood may improve rapidly.

Leukæmia and amyloid degeneration of the spleen are contraindications to splenectomy. In other conditions the choice of operation may depend entirely upon the general condition of the patient. Beyond a moderate persistent leucocytosis or lymphocytosis, and possibly a slight delay in the restoration of hæmoglobin, there are no specific effects of splenectomy in man.

It therefore appears that whatever the function of the spleen, the organ is not indispensable, and its functions may, in case of need, be performed by other parts or organs. The changes found in the bone marrow and in the lymph nodes of animals after splenectomy suggest that it is these parts that are called upon for extra work, and indicate in this way that the functions of the spleen must be, in part at least, those of the marrow and lymph nodes.

SPLEEN, SURGICAL AFFECTIONS OF THE.—Surgical interest in the spleen is increasing, for of late years quite a number of operations have been performed upon it on account of traumatism, abscess, inflammatory enlargement, tumor, or displacement.

ANATOMY.—The spleen is placed between the ninth, tenth, and eleventh ribs, being separated from them by the diaphragm, and in its upper portion also by the lung. In gunshot wounds of the spleen, therefore, the pleural cavity is frequently opened, and an abscess of the spleen may easily break into the pleural cavity. It is held in position by a suspensory ligament which attaches it to the diaphragm, and also by an extension of the greater omentum from the spleen to the stomach, which is called the gastro-splenic omentum. Behind this membrane is situated the splenic artery with its numerous branches and the splenic vein. Any incision which is made use of to expose the spleen sh uld give the surgeon easy access to these ligaments, in order that he may control hemorrhage when the ligaments are cut. Various incisions have been employed: for example, a vertical incision along the outer border of the rectus muscle, combined if necessary with a transverse incision parallel to the costal margin; or a lumbar incision similar to that employed for operations upon the kidney. In some cases it is necessary to resect portions of the ribs and reach the upper end of the spleen through tee pleural cavity.

Traumatism.—The spleen, especially if enlarged by disease, may be ruptured subcutaneously. It may also be injured by incised, gunshot, and stab wounds. If the capsule is not torn there may be hemorrhage into the substance of the spleen, producing a large hæmatoma with subsequent cyst formation. But usually the capsule is also ruptured and there is profuse bleeding into the peritoneal cavity. The chief symptoms are those of internal hemorrhage, the source of which is not likely to be suspected except in case of open wounds. A portion or the whole of the spleen may prolapse into an open wound.

The treatment is free exposure of the organ, repair of its injuries, if slight, and removal of the spleen if the injuries are extensive. Partial splenectomy has been performed, but in most cases it is more dangerous than total splenectomy; and, since the removal of the spleen has little or no permanent effect upon the health of the individual, partial resection of the organ should generally not be performed.

The mortality following removal of the spleen after traumatism is about forty per cent. for one hundred and thirty operations, two-thirds of which were performed previous to 1900. The mortality of forty-five cases treated in 1900–1901 was only twenty-eight per cent.

Abscess.—Abscess of the spleen is usually secondary, occurring in connection with endocarditis, pyæmia, typhoid fever, acute rheumatism, malaria, etc. Primary abscess may develop in a contusion of the spleen due to traumatism. Some splenic abscesses produce marked septic symptoms and terminate fatally in a short time. Others run a chronic course, the pus breaking through the capsule of the spleen and burrowing in various directions.

The proper treatment, if a diagnosis can be made, is to expose the spleen and open the abscess. If one has to pass through the peritoneal cavity to reach the spleen, it is better to fix the organ in the abdominal wound and to wait the formation of adhesions before opening the ab scess. The pleural cavity should be protected in a similar way if the incision is made high up. If the spleen is in large part destroyed it should be removed.

Cysts.—A blood clot in the spleen may become transformed into a serous cyst and the spleen may be the seat of an echinococcus cyst. Such cysts should be incised and drained, or, if the spleen is badly affected, it should be removed.

Solid Tumors.—Benign tumors of the spleen are extremely rare. The occurrence of primary carcinoma is doubtful. Metastatic carcinomatous nodules occur in the spleen, but are without surgical interest. Melano- and lympho-sarcoma are the two forms of solid tumor oftenest found. The chief symptoms are a rapid increase in the size of the spleen, with pain, in a person with no history of malaria and whose blood is unaltered. The treatment is splenectomy, which, in nine cases recently reported, had a mortality of thirty-three and one-third per cent.

Enlargements from Leukæmia, etc.—The spleen may become so hypertrophied in leukæmia, malaria, syphilis, tuberculosis, amyloid disease, interstitial hepatitis, etc., that by its very size it causes the patient great inconvenience. The removal of a leukæmic spleen is usually followed by death from hemorrhage, while the few patients who have survived the operation have not been benefited by it. In the other diseases mentioned the spleen has been successfully removed. But little benefit is to be expected from this operation if the patient is greatly weakened by a serious constitutional disorder.

Splenectomy performed upon malarial patients whose general condition is fairly good is an operation which, according to Bessel-Hagen, has a mortality of less than nine per cent., and by which many patients have been improved, although they are not protected from further malarial attacks.

Movable Spleen.—Like the other abdominal organs, the spleen may acquire an undue amount of mobility. Hypertrophy usually accompanies this condition. Like a movable kidney, it can usually be replaced, but it will not remain permanently in its proper position unless it is fixed there by adhesions. It may be found in the left iliac fossa, or even in the right iliac fossa or pelvis. It does not usually produce symptoms sufficient to render operation advisable.

A movable spleen may be sutured to the abdominal wall or it may be removed. Sutures do not hold well in its capsule, and for this reason Rydygier makes a pocket between the anterior parietal peritoneum and abdominal muscles into which he slips the movable spleen. If the movable spleen is diseased or its pedicle has become twisted it is better to remove it, since splenectomy under such circumstances has only a slight mortality and produces a radical cure.

SPONDYLOLISTHESIS. See *Spine, Diseases of.*

SPONGE.—(*Éponge fine*, Codex Med.) The household articles known by this name are the horny or silky skeletons of several species of invertebrate animals belonging to the order *Ceratosa*, in the great group *Parazoa* or *Spongiæ*. The commercial sponges are colonial in their composition, although the outlines of individuality are very obscure. They are soft, porous, gelatinous bodies, perforated by numerous openings communicating with irregular, ramifying cavities within them, as well as with digestive and respiratory chambers, and more or less regular tubes or canals. These minute chambers are lined with flagellated cells, which are probably the organs of nutrition as well as those by whose movements a constant stream of water is kept flowing into the sponge through the fine pores and out through the larger openings. Sponges are all aquatic, and those of commerce all of marine origin, growing upon rocks or other firm foundation, at a depth of from six to a hundred or more feet below the surface of the water. They are of slow growth, requiring from three to six years to attain a useful size. The mode of collection varies with the depth at which they are found, as well as with the habit and outfit of the collector; sometimes they are torn off the rocks by tongs or hooks, sometimes dredged for, but more generally they are gathered by divers from boats; these again may go down unprotected for three or four minutes at a time, or, equipped with modern diving-suits, make longer and deeper searches. Finally, the cultivation of sponges by fastening bits upon boards or sticks, and then sinking them to the bottom, has been proved practicable. When the sponges have been brought to land they are rubbed with sand or bruised to break up the soft parts, or exposed to the air until decomposition sets in, and then repeatedly washed and squeezed until they are clean and dried. Upon being marketed, they are carefully trimmed and assorted, according to kind, fineness, size, and shape, into numerous grades.

There are several distinct kinds, dependent upon the species producing them:

1. The *Levant* or *Turkey Sponge*, from *Euspongia* (*Spongia*) *officinalis* Linn., the finest and most expensive of all, from the waters surrounding the Grecian Islands, Asia Minor, Syria, etc. It has a soft, fine, very elastic texture, a light color, and great toughness of fibre. In shape it is rounded, tuberculated, lobed, hemispherical, cup-shaped, or irregular; it is very free from its gelatinous flesh when prepared for the market.

2. The *Zimocca Sponge*, from *Euspongia Zimocca* O. Schmidt; also a fine, strong, valuable sponge, but harsher to the feeling than the preceding, and not nearly so expensive.

3. The *Mediterranean Bath Sponge*, from *Hippospongia equina* O. Schmidt; in large, soft, rounded masses, with a loose texture and very large reticulating canals.

Besides these, this country is supplied in great abundance with cheap sponges from the West Indies; they are very inferior in texture and durability to the Mediterranean products: they are:

4. The *Reef Sponge*, *Euspongia officinalis tubulifera*, the common, cheap, fine "slate sponge." It is coarser, less elastic, and very much more tender than the Turkey sponge, and is of more or less conical shape, with a broad, cut base.

5. The *Sheepswool*, *Velvet*, and *Grass Sponges*, from various species of *Hippospongia*.

Composition.—Sponges contain a considerable quantity of fine sand, and sometimes pebbles, entangled in their meshes, which can generally be removed by mechanical means; there is also a varying amount of calcareous concretions or fragments, which stick more tenaciously and often have to be dissolved by dilute acid. These being removed, the remainder is nearly all a peculiar elastic, durable, nitrogenous substance called *spongin*, closely related in composition and texture to silk. Besides this, there are a little iodine, bromine, salt, etc.

Uses.—These are mostly mechanical, and familiar to every one. Carbonized sponge, *Spongia usta*, now obsolete, used to be given for the same conditions for which iodide of potassium is now used, and owed its value to the presence of that element.

In surgery, sponges were for a long time used for packing and dilating cavities, and as absorbers of blood in operations, but the general acceptance of aseptic methods in surgery has caused them to be looked upon less favorably than formerly. For surgical operations the fine, soft, Turkey sponges, though dear, are the best.

Sponge tents, now but little used, are made by soaking fine, tough sponge in melted cacao butter, or in mucilage or alcohol, and winding very hard to a cylindrical shape with strong twine; when dry or cold the cord is removed and the surface is filed or pared to shape.

Ether sponges are fine Turkey sponges of large size, requisite fineness, and of a regular cup-shape. No inhaler has yet been made so safe or comfortable to the patient as these, but they are wasteful of ether.

SPRING LAKE WELL.—Ottawa County, Michigan.

POST-OFFICE.—Spring Lake. Hotel.

Spring Lake is a station on the Detroit and Milwaukee Railroad, three miles east of Grand Haven. The town is located on a beautiful sheet of water of the same name, five miles long and one mile wide. The resort owes its rise to the citizens of Chicago, who frequent it in considerable numbers (Walton). The following analysis was made by Prof. C. G. Wheeler: One United States gallon contains (solids): Sodium bicarbonate, gr. 0.05; calcium bicarbonate, gr. 0.13; magnesium bicarbonate, gr. 0.01; iron bicarbonate, gr. 1.01; sodium sulphate, gr. 46.70; sodium chloride, gr. 405.53; potassium chloride, gr. 4.29; manganese bicarbonate, gr. 0.05; calcium chloride, gr. 113.42; magnesium chloride, gr. 36.20; bromides, gr. 2.17; organic matter, gr. 18.29; and small quantities of lithia, alumina, silica, and ammonia. Total, 628.37 grains. In chemical composition this water resembles that of the Elisenquelle, of Kreutznach.

James K. Crook.

SPUNK.—*Fungus Chirurgorum*, Ph. G.; *Agaric de Chêne*, Fr. Cod.; *Surgeons' Agaric, Touchwood*, E.; *Amadou*, Fr. The prepared tissue of *Polyporus fomentarius* or of *P. igniarius* Fries (fam. *Agaricineæ*). These are rather large species of fungi, parasitic upon the trunks of forest trees, especially of oaks and beeches. They are attached by broad bases and expand horizontally in large, roundish, hoof-shaped masses of corky texture and reddish or grayish-brown color. The upper surface is convex and marked by a series of distinct concentric rings, each indicating a year's growth. The under side is flat. The first-named species is said to yield the best product. The fungus has its upper and lower surfaces trimmed off, is softened in water, beaten with a wooden mallet into a tough, soft, and flexible buckskin-like sheet, and dried. In this condition it will absorb more than twice its weight of water. The uses of spunk are purely surgical. Before the days of modern styptic and absorbent appliances, it was largely depended upon for checking hemorrhage, through its mechanical properties, as lint and similar substances are now used. Its softness and flexibility also adapted it well to use for padding purposes. In this country its use has almost entirely ceased.

Soaked in a solution of nitre or chlorate of potassium, it becomes very inflammable, and such a preparation was enormously used as tinder before the days of matches.

W. P. Bolles.

SPUTUM is the term employed to designate the portion of the expectoration that is derived from the trachea, bronchi, and their ramifications. It is sometimes used to include the secretions from the upper air passages, and even to include the saliva and buccal secretions; it is better, however, to employ the term expectoration to designate the collective material discharged from the mouth and to use the term sputum in the restricted sense above indicated.

For its *collection*, special receptacles are provided. The simple paper spit-cups are inexpensive and convenient; there are also metal cups adapted for carrying in the pocket. For the hospital ward a simple porcelain cup is much used. The principle to be observed in disease is that all the expectorations shall be collected and disinfected or destroyed by burning. This is particularly important in the case of tuberculous sputa, the dried particles of which are so apt to become mingled with the dust in the air and infect those who inhale them.

The *amount* of the sputum in health is very small, scarcely more than a few cubic centimetres in twenty-four hours, while in disease it may increase up to 1,000 c.c. or more. The amount and character are dependent on the nature and extent of the disease process, a fact which renders observations of the sputum of value in clinical practice.

As regards *appearance*, sputa, if homogeneous, are recognized as mucoid, purulent, serous, or sanguineous, for reasons which these terms suggest. Most sputa, however, are admixtures of two or three of these types and are designated accordingly; *e.g.*, the muco-purulent sputum in many cases of bronchitis.

The consistence varies from liquid to extremely tenacious, according to the amount of mucus; serous and hemorrhagic sputa and purulent sputum, when composed of pure pus, are liquid, while a pure mucoid sputum exhibits a high degree of tenacity. I do not know that it has been determined whether the albuminoid basis is true mucin, as in saliva, or a nucleo-proteid.

The *color* of sputa is subject to great variation. If mucoid in character, they are transparent and nearly colorless; when the number of leucocytes is considerable they are opaque, yellowish, or, in case of nearly pure pus, greenish at times from the presence of the Bacillus pyocyaneus. This latter color may also be imparted by bile pigment in icterus and in perforation of a liver abscess into the lung; if the abscess is amœbic, the sputa have the color of anchovy sauce; unchanged blood imparts various degrees of reddish coloration, which may be characterized as rusty, prune-juice, bright or dark red, according to the condition; methæmoglobin, hæmatin, and hæmatoidin formed by decomposition of the hæmoglobin, impart colors varying from bread crust to chocolate or brownish-red. Sometimes decomposed blood gives a greenish or yellowish hue.

Pure mucoid, serous or sanguineous sputa are usually without *odor*, but where there is admixture of purulent products a slightly sweetish odor is observed; while in sputa containing pure pus and products of putrefactive decomposition a fetid odor is present, sometimes exceedingly offensive.

Macroscopic examination may be conducted by observing the material, spread in a thin layer, either between glass plates or in a petri dish, against a dark background.

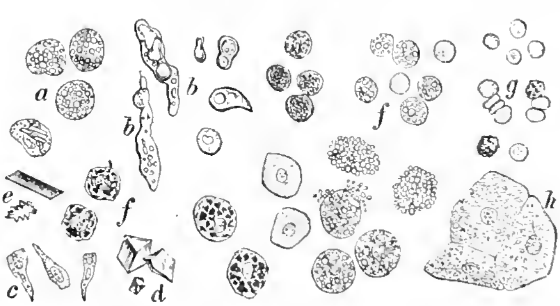

FIG. 4468.—Cells and Crystals of the Sputum. *a*, Alveolar epithelia; *b*, myeline drops; *c*, ciliated epithelia; *d*, calcium carbonate crystals; *e*, hæmatoidin; *f*, leucocytes; *g*, red blood corpuscles; *h*, squamous epithelia. (Magnified.)

In this way fragments of lung tissue, elastic fibres, fibrinous casts, spirals, and particularly the cheesy masses of tuberculosis and actinomycosis may be observed. For the recognition of spirals and casts of the bronchi it is also of service to observe the sputum when suspended in a considerable quantity of water.

Microscopic examinations are conducted: (*a*) By the direct examination of selected portions under the microscope, a procedure particularly valuable in examinations for crystals, the various epithelia, and for pus. (*b*) By the examination of the sediment obtained by centrifugalizing the sputum after it has been diluted with an aqueous solution of sodium hydroxide (about two- or three-per-cent. strength), and warmed. This sediment is especially adapted for the detection of elastic fibres. (*c*) By the examination of stained smears, which may be prepared as follows (W. H. Smith). Smear a selected portion thinly and uniformly on a cover-glass, fix by heat (passing through the flame three times without burning), cover with aniline-gentian violet, heat to steaming, wash off with Gram's iodine solution, cover with the solution and steam, decolorize as much as possible with ninety-

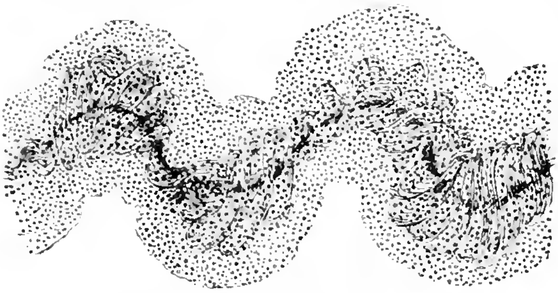

Fig. 4469.—Curschmann's Spirals. (Magnified.)

five-per-cent. alcohol, wash a few seconds in alcohol-ether, wash in water, stain for a few seconds in strong aqueous eosin, wash with Löffler's methylene-blue, cover with this, steam, decolorize slightly with ninety-five-per-cent. alcohol, wash in absolute alcohol, then in xylol, and mount in Canada balsam. In this preparation red blood corpuscles, cell protoplasm, eosin granules, cilia of epithelial cells and capsules of bacteria are stained red, nuclei blue, Gram-staining bacteria black or deep violet and Gram-decolorizing bacteria blue. Tubercle bacilli are not differentiated. (*d*) By the examination of smears stained for tubercle bacilli in the manner described in the article on *Bacteriological Technique* in the APPENDIX.

Abscess.—When the abscess empties itself through a bronchus there is likely to be a considerable quantity of liquid, purulent sputum with a more or less offensive odor. This same periodicity in the appearance of pus is observed in empyema and bronchiectasis, but elastic fibres, which are present in abscess, are usually absent in these conditions. Crystals of cholesterin, fatty acids, leucin, tyrosin, or hæmatoidin may accompany the large number of pus cells; the blood pigment, if intracellular, probably indicating some previous hemorrhage, if free a discharging abscess from a neighboring organ. In hepatic abscess, bile pigment or ameba coli may be present, and the sputum may be in part mucoid or watery. The presence of hooklets of Tænia echinococcus or ova of Distoma pulmonale or Distoma hæmatobium indicates infection with these parasites.

Actinomycosis.—The presence of the ray fungus in small (one-tenth to one-fortieth inch in diameter), round, yellowish masses, glistening and granular in appearance, is pathognomonic of the pulmonary seat of this disease. They are not always to be found. The general characters of the sputum are those of a chronic putrid bronchitis.

Asthma.—The amount of the sputum varies. It is apt to be more copious at the end of the attacks, and to be viscid, mucoid, and whitish, or pink from blood. Its occurrence in small pearl-like masses is quite characteristic. Unfolded, these masses are seen to be Curschmann's spirals, which are more common early in asthma than in any other disease, and aid in differentiating true asthma from the reflex type. Charcot-Leyden crystals are almost constantly present; eosinophiles are usually numerous, and free eosin granules may be present. Occasionally leucocytes and epithelial cells are found which contain yellow and brown masses of pigment, probably derived from the blood.

Bronchiectasis is accompanied by copious, intermittent expectoration which may be odorless, but ordinarily has a rancid fœtor, different from that of gangrene, is apt to be darker in color than in simple bronchitis, oily in consistence, has a tendency to form nummular masses appearing like coins (Dittrich's plugs), and casts of the minute bronchial tubes. Pus is usually present, and crystals of hæmatoidin, cholesterin and fatty acids, and Charcot-Leyden crystals may be found. Unless there is ulceration (abscess formation) elastic fibres are absent. Occasionally the sputa contain inspissated or even calcified portions.

Acute Catarrhal Bronchitis.—In the early stages the sputum is scanty and mucoid or sero-mucoid. Later, it becomes more abundant and muco-purulent, sometimes sanguineous, the change in character often being accompanied with a fall in temperature. After the lapse of two weeks the expectoration may take on the character seen in chronic bronchitis. When the bronchial capillaries are especially involved in the disease process, there is less admixture of air, and consequently a tendency for the sputa to sink in water; when the disease is limited to these smaller bronchial tubes the sputa may be scanty or absent. Microscopically, the muco-purulent sputum contains many pus cells, eosinophiles and ciliated, cuboidal, or alveolar epithelia, according to whether the larger or smaller bronchi or the alveoli are involved. The bacteria present usually include one or more of the pus organisms, and when the disease is secondary to some infective disease, *e.g.*, influenza or typhoid, they may include the specific agent of this infection as well. Diphtheria bacilli are usually not present in the bronchitis which sometimes accompanies this disease.

Chronic Catarrhal Bronchitis.—The sputum is extremely variable, that of the dry type of the disease being scanty and perhaps occurring as tough pellets of mucus, while the expectoration of the moist type is more abundant, sometimes copious, and either serous (thin) or purulent (thin or thick) in character. The purulent secretion is commonly yellowish-green in color. Microscopically there is commonly little of interest to be seen; numerous pus cells, a variable number of epithelia, usually cuboidal, bacteria, and ordinarily one or more of the various pus organisms, are present. In rare instances the fetid odor of the sputum justifies us in characterizing the disease as putrid bronchitis. The sputum is then usually thin, whitish, and may contain the yellow, dirty masses the size of peas which come from the smaller bronchi and are known as Dittrich's plugs. Microscopically these may contain fatty acid crystals, degenerated epithelia,

Fig. 4470.—Charcot-Leyden Crystals. (Magnified.)

spirals, and Charcot-Leyden crystals. Fetid sputum more frequently denotes bronchiectasis, gangrene, abscess, phthisical cavities, or empyema.

Plastic Bronchitis.—This is characterized by fibrinous masses, the recognition of which in the sputum forms the only means of diagnosis. If they come from the larger bronchi they do not necessarily present any recognizable form, but when they come from the smaller tubes they appear as casts, corresponding to the ramifications of the tube. In the sputum they may be mere spherical masses more or less obscured by the mucus and pus, but when floated in water their true character may be recognized. Their presence should be suspected whenever expectoration is accomplished by severe effort. In the acute process the sputum, aside from the presence of the casts, is much like that of acute catarrhal bronchitis. Curschmann's spirals and Charcot-Leyden crystals may be present. The chronic form of the disease is even more likely to be overlooked, as the fibrinous masses are more apt to be masked by the other constituents of the sputum, which presents the ordinary features of that which belongs to chronic catarrhal bronchitis.

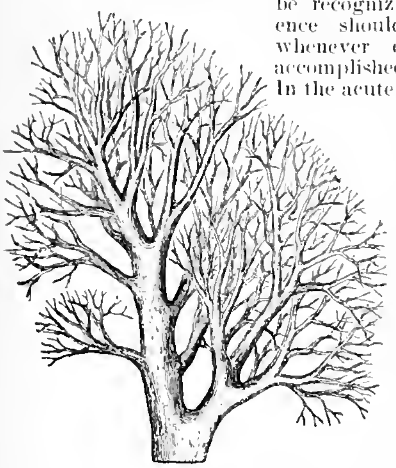

FIG. 4471.—Fibrinous Cast of Chronic Plastic Bronchitis. (Two-thirds actual size.)

An *empyema* that discharges into the bronchi gives rise to purulent sputa which may have an offensive odor. They differ from the sputa of bronchiectasis in the absence of oily appearance, mucous admixture, fatty acid crystals, and fibrinous casts of the minute tubes. The prevailing infecting agents are the Streptococcus pyogenes and the pneumococcus, the former being more frequent in children. The presence or absence of tuberculous infection is of importance.

Gangrene of the lung announces itself by a horribly fetid odor, less pungent than that observed in bronchiectasis. The sputum is apt to be tinged with blood, the color often suggesting prune juice, but being at times chocolate-colored from the development of hæmatoidin when the sputum is retained for some time before being discharged. It is frothy, in part liquid, in part mucopurulent, and may contain small portions of gangrenous lung, dark or greenish in appearance. The débris from the lung tissue does not always contain elastic fibres, as they apparently pass into solution under the strong solvent action of the ferments present. Putrefactive bacteria abound, and forms belonging to the other groups of fungi may be present. Even infusoria of the monad and cercomonad varieties are sometimes observed; they occur as minute, yellowish, slowly moving droplets. Robinowitsch in one case observed a bacillus not identical with, but morphologically resembling, the tubercle bacillus.

Active Hyperæmia of the Lungs.—The sputum is characteristic, being serous, not infrequently slightly sanguineo-serous, clear, containing the serum proteids in solution, and, in contrast to other sputa, having a high specific gravity (1.025-45).

Passive Hyperæmia of the Lungs.—As this is accompanied by a chronic catarrhal bronchitis, the sputum presents the characters of that disease plus two additional features induced by the chronic hyperæmia, namely, the presence of blood pigment, which may be in all stages of alteration, and many alveolar epithelia containing hæmatoidin crystals.

Influenza.—The pulmonary invasion is characterized by the presence of the specific bacillus in the sputum. Early in the acute stage it will be found free in the sputum, but later it is found only in the pus corpuscles. The clinical manifestations are those of bronchitis, either acute or chronic, or of bronchopneumonia. It may be a secondary invader in lobar pneumonia and even in phthisis. The general characters of the sputum, aside from the presence of the influenza bacillus, are in general those common to the particular clinical type of the disease, though in pneumonia it is bronchitic rather than pneumonic in character. When isolation of the bacillus is desired, the following method of W. H. Smith may be employed: A small portion of the fresh sputum is suspended in sterile bouillon, and one loopful of this bouillon is spread evenly over the surface of an agar slant; then a second drop is likewise spread on an agar slant, the surface of which has been smeared with human blood. The influenza bacillus does not grow on the first agar slant, but appears on that which is smeared with human blood—after remaining at 37° C. (98.6° F.) for forty eight hours or less—in the form of minute colonies, frequently unrecognizable without a lens, and showing in smear preparations the morphology of the influenza bacillus. Stain by floating for five to ten minutes in carbol-fuchsin, one part diluted with twenty of water.

Malignant Neoplasms.—The character of the sputa depends upon the condition which may be produced in the lung by the disease process—*i.e.*, upon the bronchitis, bronchiectasis, œdema, ulceration or gangrene, that may be present. It may contain lung débris, including pieces of the neoplasm, and may present peculiar appearances, sometimes resembling red currant jelly, while in some forms of sarcoma it appears bright green.

Catarrhal Pneumonia.—In this disease the sputum is less characteristic than in lobar pneumonia. It may present the character of the expectoration of an acute bronchitis, with which the disease is frequently associated, or it may be scanty and mucoid. It may be tinged with blood, generally an unfavorable sign, but it has not the characteristic sanguineous character seen in lobar pneumonia. Mixed infection being the rule, more than one organism is to be expected in the sputum, though early in the disease the primary agent, most commonly the pneumococcus, streptococcus, staphylococcus, or the pneumobacillus, in the order named, is the only or chief intruder. Broncho-pneumonias, which are pulmonary complications in specific diseases, are apt to have the organism causing the disease as the primary agent, and accordingly this organism appears in the sputum; but the specific organism may be a secondary invader.

Croupous Pneumonia.—During the first twenty-four hours the sputum may be wanting, or it may consist only of small mucoid masses. In the stage of red hepatization it presents pathognomonic characters, appearing "rusty" from blood and being exceedingly viscid and tenacious. As regards the quantity of the sputum, as much as from 100 to 300 c.c. is commonly raised in a day. Microscopically it shows red blood corpuscles in all stages of degeneration, alveolar epithelia, which are in large number in desquamative pneumonia, and sometimes small fibrinous casts. The stained smears show the infecting organisms if they are the exciting cause of the disease. The presence of the pneumococcus in abundance is presumptive evidence of the disease, and is an especially valuable indication in central pneumonia. The sputum is to be watched for complications. A sudden increase of serous fluid indicates œdema; a large quantity, dark brown in color, perhaps with elastic fibres, indicates necrosis; while a copious purulent discharge points to the existence of an abscess or a bronchiectasis and the fetid character to gangrene.

Pneumonokoniosis is usually recognized from the characteristic expectoration. The general nature of the sputum is that due to the associated condition, viz., chronic bronchitis, or chronic interstitial pneumonia with its usually copious, muco-purulent, or sero-purulent sputum, not infrequently hemorrhagic and sometimes fetid, or tuberculosis. The inhaled dust particles may be free or may be lodged within the leucocytes or mucous and epithelial cells. In anthracosis the color is so dark as to lead to the characterization "black spit"; in siderosis the oxide-of-iron color is seen; while in chalicosis the condition is recognized by the angular particles of silica seen under the microscope.

Pulmonary Tuberculosis.—In the acute miliary form, as in early acute bronchitis, the sputum is scanty and mucoid, tubercle bacilli usually not being found, certainly not till softening of the tubercles occurs. In acute pulmonary phthisis tubercle bacilli may be present in enormous numbers, the expectoration being rusty and then muco-purulent, and containing elastic fibres when a process of softening has set in; these features and the presence of the tubercle bacilli constituting the marks which distinguish the disease from ordinary pneumonia. In chronic phthisis the expectoration is variable, the variations in its amount and nature from time to time giving some indication of the activity of the disease. Its heterogeneity is characteristic, some portions being but slightly purulent, others yellowish, purulent, and forming nummular with here and there cheesy masses and possibly even calcareous particles. Microscopically, the important features are the tubercle bacilli and elastic fibres, together with the presence of the purulent organisms that are secondary invaders. Occasionally Curschmann's spirals are present. Nuttall estimates that four billion individual tubercle bacilli may be present in the expectoration in twenty-four hours. Lartigau states that only from ten to fifteen per cent. of those present are ordinarily alive, and that dead bacilli alone may be present and persist in the sputum for weeks. It is generally believed that the forms that take the stain irregularly, presenting a beaded appearance from the presence of unstained spaces, are attenuated in their virulence. *E. E. Smith.*

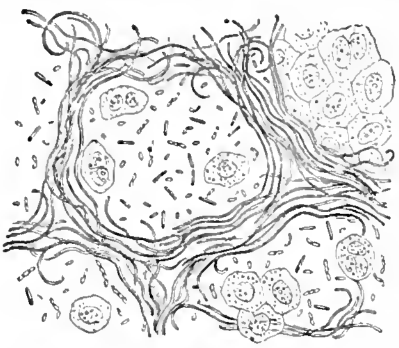

FIG. 4172.—Elastic Fibres Occurring in the Sputum. (Magnified.)

SQUILL.—(*Scilla*, U. S. P.; *Bulbus Scillæ*, P. G.; *Scilla*, Cod. Med.) The bulb of *Urginea maritima* (L.) Baker (fam. *Liliaceæ*), deprived of its dry, membranaceous outer scales, and cut into thin slices and dried, the central portions being rejected.

Squill is derived from a perennial herb of the Mediterranean coast region, especially in Spain. The bulb is large, four or five inches long, globular-ovoid, covered with two or three dry, reddish or gray, papery scales, and made up within of numerous thick fleshy ones. There are two varieties, the white and the red, distinguished by the color of the outer tunics of the bulbs. For medicinal use, the bulbs are collected in the latter part of summer, sliced transversely, dried in the sun, and the papery scales winnowed out. To produce the best article, only the outer scales should be preserved. The presence in the drug of the less valuable central portion is indicated by the relative shortness and thinness of the strips, and their higher degree of curvature. Squill occurs in irregular, more or less curved segments several centimetres (about one to two inches) long and 4–8 mm. ($\frac{1}{6}$–$\frac{1}{3}$ in.) broad, thinner in one direction, with two to four sharp edges; yellowish-white or somewhat reddish, slightly translucent, brittle, and pulverizable when dry, tough and flexible when damp; inodorous and of a mucilaginous, bitter, and acrid taste.

When consisting of very narrow, short, closely curved or coiled segments, from the inner portion of the bulbs, the product should be rejected.

Structurally, it consists of a simple parenchymatous tissue, loaded with mucilage and containing numerous oxalate-of-lime crystals, and traversed by occasional vascular bundles.

CONSTITUENTS.—Besides a large amount of gum, some sugar, the unimportant dextrin-like substance sinistrin, etc., squill contains as its active constituents several glucosides, the constitution and relations of which are not yet well known.

Scillitoxin is amorphous, light brown, soluble in alcohol, not in ether or water, a cardiac poison resembling digitalis; *scillipikrin*, a yellowish-white, amorphous, hygroscopic powder, similar to the above but less active; and finally *scillin*, of no medicinal qualities.

ACTION AND USE.—Few medicines outrank squill in antiquity, it being mentioned by nearly all medical writers from the earliest down. It possesses in a measure the heart-slowing and diuretic action of digitalis, for which it is occasionally substituted and with which it is more frequently given as an adjuvant. As a slightly depressing expectorant it is a common ingredient of cough preparations. Large doses (from six to twelve grains) occasion vomiting and purging.

It is stimulant, or in overdoses irritant, to mucous membranes; hence it acts as a direct diuretic in its passage through the kidney, in addition to its indirect diuretic effect through increased blood pressure. Hence, also, the frequent production of bloody or suppressed urine, and bloody stools and other indications of intestinal inflammation, in cases of poisoning.

ADMINISTRATION.—Squill is difficult to powder, apt to cake up when powdered, and seldom given in substance.

The following preparations are official: Fluid Extract (*Extractum Scillæ Fluidum*, strength, $\frac{1}{1}$), dose, ♏ i.–ij.; Tincture (*Tinctura Scillæ*, strength, $\frac{15}{100}$), dose, ♏ viij.–xxiv.; Vinegar (*Acetum Scillæ*, strength, $\frac{1}{10}$), dose, ♏ xv.–lx.; Syrup of Squills (*Syrupus Scillæ*), dose, 4–8 c.c. (ʒ i.–ʒ ij.). The Compound Syrup (*Syrupus Scillæ Compositus*) is rather a preparation of antimony than of squill. *Henry H. Rusby.*

STAFFORD MINERAL SPRING.—Jasper County, Mississippi.

POST-OFFICE.—Vosburg. Small hotel.

ACCESS.—Viâ the "Queen and Crescent" route to Vosburg, thence one mile and a half southeast to spring.

The location is a romantic one, surrounded as it is by Indian mounds and relics, and shaded by graceful and towering gums, sycamores, poplars, and pines. The Choctaws gave the name of Bogohama ("Water of Life") to the spring; hence it is inferred that they used it for medicinal purposes. Its properties have been known to the whites, however, only during the last five or six years. At present there is, within one hundred yards of the spring, a large, well-kept boarding-house, where guests will find all arrangements for their comfort. It is the intention of the company controlling the spring to build a large and commodious hotel, with all modern conveniences, to accommodate the rapidly increasing number of guests. The many natural advantages of the spot in the way of charming scenery, salubrious climate, and mineral waters will no doubt serve to make it one of the popular spring resorts of the country in the near future. The following analysis of the water was made by Prof. A. L. Metz, of the Tulane University, New Orleans, in 1892: One United States gallon contains (solids): Sodium chloride, gr. 0.96; sodium carbonate, gr. 0.41; potassium sulphate, gr. 0.98; magnesium bicarbonate, gr. 0.97; calcium bicarbonate, gr. 13.69; calcium sulphate, gr. 0.56; ferrous (iron) bicarbonate, gr. 0.24; alumina, a trace; silica, gr. 1.99; no organic matter. Total, 19.80 grains.

The analysis shows a very good calcic water, with ferruginous properties. The entire absence of organic matter adapts it for table and domestic use. The water has tonic and diuretic properties, and ought to be useful in the diseased or disordered conditions to which this class of waters is applicable. It has been found to render excellent service in Bright's disease of the kidneys and in diabetes, bladder disorders, and other conditions. The water is bottled and sold throughout the United States.

James K. Crook.

STAFFORD SPRINGS.—Tolland County, Connecticut.

Post-Office.—Stafford Springs. Accommodation in private families.

Access.—Viâ New London and Northern Railroad from junctions at Willimantic, Conn., and Palmer, Mass.

This historical old spring has been known as a resort since the year 1750, and its waters were celebrated among the aborigines for many years prior to that date. During the latter part of the eighteenth and for many years of the nineteenth century the place was held in high favor throughout New England and the neighboring States. The records of the guests of former days are filled with the names of people distinguished in all the walks of life. Among these names we find those of Dr., afterward General, Joseph Warren, and President John Adams. The development of other springs has detracted from the prestige of Stafford, but under an enterprising management the resort will no doubt again acquire a prominent place in public favor. Heretofore the water could be obtained only at the spring, but it is now bottled and shipped to any desired point. The country about Stafford Springs is diversified by hills and valleys, and the landscapes are very pleasing during the summer months. The flow of water from the spring amounts to about fifty-five gallons per hour. We are indebted to Dr. J. M. Sheehan for the following analysis by Lewis Norton, Ph.D., of the Massachusetts Institute of Technology. One United States gallon contains (solids): Sodium chloride, gr. 0.31; potassium sulphate, gr. 0.21; sodium sulphate, gr. 0.96; sodium bicarbonate, gr. 0.46; sodium phosphate, gr. 0.22; iron peroxide, gr. 0.67; iron protoxide, a trace; alumina, gr. 0.11; lime, gr. 0.41; silicic acid, gr. 2; magnesia, volatile matter, etc., gr. 1.75. Total, 7.10 grains. Carbonic-acid gas, 25 cubic inches.

The water is clear and sparkling and excellent for table purposes. It has attained its greatest reputation in the treatment of blood and skin affections. It is said to be actively diuretic.

James K. Crook.

STAMMERING AND STUTTERING are terms often used to denote speech defects in general, without reference to their origin. Technically the word stuttering should be limited to tonic or clonic spasms of the muscles concerned in phonation and articulation. Stammering is imperfect articulation, not spastic, but due to malformation of the organs of speech, or to imperfect innervation of the muscles used in articulation.

Stammering has nothing to do with the joining together of sounds, but is the inability to render them properly, even when given alone. The terms stammering and stuttering are confused, always in the older writings, often in more recent ones.

Stammering must be distinguished from aphasia. That has to do with neither the production nor the joining together of sounds, but with the construction of syllables and words as a whole. It is caused by the disabling of those parts of the cerebral cortex which contain the sensory or motor speech memories, or of the fibres connecting these with other parts of the nervous system.

Aside from occasional faulty pronunciation, to which every one is more or less liable, there are many cases of stammering in which the trouble is due to carelessness and inattention, fixed by habit. These cases are important as well from a diagnostic as from an educational standpoint, as they may be mistaken for cases of acquired speech defect, especially when organic brain disease co-exists with them.

The capability of pronouncing different sounds is largely a matter of race and training. Every one stammers in a foreign language, if he undertakes to learn its new sounds after his habits of speech are formed. Thus the German *ch*, French nasals, and Italian *r* are seldom perfectly acquired by an adult. But, according to Kussmaul, "the most choking guttural of a Swiss throat modestly retires before the vomiting throat sounds of an Arabian."

We may divide our subject into stammering from habit or carelessness, organic defect of the organs of speech, and disease of the nerve centres. The speech defects in all these cases may be identical, and in order to distinguish one from the other a careful examination and attention to the history are often necessary. A complete list of sounds which may be mispronounced is not possible. It will be sufficient to indicate a few of the more common ones.

The mispronunciation of the letter *r* is called rhotacism or burring. This letter has the same general sound, but is produced in various ways by different nations. In English-speaking countries it is formed by approximating the sides of the tongue to the roof of the mouth, but in certain localities it is often slurred. Its place is then taken by a *ŭ* or *ä* sound. In Southern England it is produced by the tip of the reverted tongue. In Italy it is made by a rather prolonged and rapid vibration of the tip of the direct tongue against the palate. The Italian nobility profess to be unable to produce this sound, and use the English *r*. In Northern Germany it is made by the uvula, in Sweden by the glottis. It is evident that correct speech in one country is stammering in another; *e.g.*, the use of the uvula in pronouncing the English or Italian *r*. Again, the ordinary sound may be replaced by an entirely different one. In this case *l* or *w* is usually employed. This is commonly done by children, who acquire the *r* sound among the last.

L is often mispronounced, *r*, *d*, *t*, *y*, etc., being used instead. This is called lambdacism. *L* should be made by placing the tip of the tongue against the hard palate, and then phonating so as to make a continuous sound, the air escaping at the sides of the tongue. If the air does not escape, the explosive *d* is produced instead; if the tongue does not touch the palate, the half vowel *y* is made, and so on.

Lisping, or sigmatism, is the most common form of stammering. It consists in giving *s* a wrong sound, usually that of *th*, by carrying the tip of the tongue too far forward, so as to touch the upper teeth. In this way both the hard and soft sounds of *s* are replaced. This occurs even among the Germans, who have no *th* sound in their language.

Gammacism is the mispronunciation of the letter *g*. It is sometimes hardened into *k*, sometimes changed to *d*, especially by children.

Stammering of vowel sounds consists in slurring them so that they lose more or less of their individual character. A certain degree of this is in conformity with the spirit of the English language; in fact, many of our different vowels are, under certain circumstances, rendered in exactly the same way, *e.g.*, in bird, burn, and father, and in bun and monkey. When carried beyond the degree sanctioned by general usage, this is stammering.

Hesitating speech with interpolation of a *ŭ* sound is popularly called stammering, but usually is simply a device for gaining time.

All the above varieties are often simply the result of habit. Examination shows that the patient has always spoken in the same way, and reveals absence of other symptoms of disease.

Treatment is simply education. The patient should be carefully shown how to place his articulating apparatus so as to produce the required sound. Sometimes it will be found that he can readily do this when shown how. It is then only necessary to insist that he take the requisite amount of trouble every time he speaks. Other patients, especially adults, have the greatest difficulty in accustoming themselves to the change. The great point is to begin early. The acquiring of a new sound in his own or a foreign language is to an adult often an impossibility.

Organic defects of the organs of speech may be congenital or acquired, and lead to the same vices of articulation mentioned above, but often in a much higher degree; at the same time the voice may be changed in quality, acquire a nasal twang, etc. The production of the normal sounds is then an impossibility, even if the patient is instructed how to do it.

Harelip interferes especially with the pronunciation of the labials, cleft palate and uvula with the gutturals, besides giving a nasal twang to all sounds.

The tongue may be bound to the floor of the mouth by a short frænum, causing thickness of speech and imperfect utterance of the linguals

All these conditions must be ascertained by inspection. The treatment is surgical, followed at an appropriate interval by instruction in speaking.

Excision of the tongue for cancer interferes less with articulation than might be expected; *d, t,* and *l* are the only sounds which are lost, and the patient is able in a little while after the operation to make himself understood.

The larynx has little to do with articulation. Disease there causes aphonia. Even after its total extirpation patients have acquired the power to speak, setting in vibration the column of air contained in the pharynx.

Nervous diseases may cause literal as well as other defects of speech. The diagnosis must be based on a careful review of all the symptoms. The mode of development of the stammer is of the greatest importance.

Most characteristic in this respect is the defect in bulbar paralysis. In this disease the ganglion cells in the medulla oblongata are destroyed one after the other. The process usually begins in the nucleus of the hypoglossal nerve, and extends to the facial, spinal accessory, and glosso-pharyngeal. Wherever it extends it is accompanied by a paralysis of the muscles supplied by the affected ganglion cells; and as the tongue, lips, and palate are successively involved, the sounds formed by these parts become indistinct and finally disappear. In this way the patient loses the power to form the linguals; paresis of the lips causes at first disappearance of *o* and *u*, later of the explosives *b, p,* and *m*; when the disease extends to the uvula the nasal cavity is not properly shut off, and, besides the nasal quality which is given to it, the voice becomes much weaker from the large quantity of air which escapes through the nose. At the same time the lips, tongue, and palate are paralyzed for ordinary movements to a corresponding degree; whistling is impossible, swallowing difficult, and there is marked atrophy of the muscles with reaction of degeneration. There is no true aphasia nor amnesia, but speech may finally be entirely lost by the successive elimination of its component sounds. These changes are eminently progressive in character and usually slow; the symptoms may appear rapidly, from hemorrhage or embolism. During the prodromal stage, with heaviness of speech and occasional difficulty of articulation, diagnosis is not easy.

In paretic dementia the symptoms are more complicated. The disease process is scattered through the greater part of the nervous system. If the medulla is involved there may be much the same defects of articulation as in bulbar palsy, but they never reach so high a degree. At the same time there is apt to be marked tremor of the face and tongue, elision of syllables, loss and misapplication of words, and weakening of the logical powers. In typical cases it may be possible to make the diagnosis from the speech alone. It should be remembered, however, that stammering and stuttering may coexist with congenital mental defect and simulate this condition closely. The occurrence of delusions of grandeur and the somatic symptoms will then decide.

Multiple sclerosis may or may not cause disturbances of speech, according to the location of the areas of induration. When the cerebrum is affected it is apt to be so in the subcortical portion, and the fibres coming from the left third frontal convolution may be involved. If they are involved, they may be cut across, and aphasia will then result. Usually they persist, altered more or less by the sclerosed tissue around them, motor impulses are transmitted through them with difficulty, and speech becomes measured and slow. This is called scanning. At the same time there is irregularity in the force with which syllables are brought out. The voice is monotonous and on a high key. But areas of sclerosis may occur below the basal ganglia and cause true stammering.

In ordinary right-sided hemiplegia speech may suffer from implication of the fibres of the knee of the internal capsule, and possibly from affection of the basal ganglia. Clinically, when aphasia of this origin passes off there is generally left an indistinctness of articulation which coexists with partial paralysis of the tongue and lips. This is not observed with aphasia of purely cortical origin.

The treatment of these forms of stammering is simply the treatment of the diseases which cause them.

Functional diseases are not often the cause of a literal dysarthria. In chorea, if the lips and tongue are affected, speech is irregular or absent during the spasm. This, however, is not the result of any disorder of the central speech mechanism.

Stuttering is a functional speech defect, consisting of clonic or tonic spasm of the muscles of respiration, phonation, and articulation, induced by the attempt to utter articulate sounds.

The intensity of the spasm varies greatly in different cases, from a scarcely noticeable impediment in speaking to an attack which renders speech for the moment impossible. The disturbance results in closure of the air passages, which is with difficulty overcome by the patient, and usually occurs in connection with the explosive consonants, in producing which there is normally a closure either by the lips, by the tongue, or by the soft palate. It may, however, occur with the pure open sounds, or before a sound has been uttered, in which case the spasm originates at the glottis. There may or may not be repetition of the offending sound, but there is likely to be when it is one of the explosives.

The attacks occur irregularly, and are much influenced by circumstances. Thus a stutterer may be able to converse easily with his friends, may be able to carry on an ordinary conversation, but have trouble in telling a story or in making any prolonged effort at speech. One may stutter only when tired or slightly out of health. Stutterers are usually exempt when whispering or singing, but this rule has frequent exceptions.

Stuttering has been known from the earliest times, but has been generally confused with other speech defects, so that it is often impossible to tell whether an account relates to this or to aphasia, or to stammering. It differs from the latter in origin, is never due to organic defect, nor entirely to carelessness, is intensified when the patient's attention is directed to his speech, or when he is embarrassed, and it is only occasional, while stammering is regular. Under favorable circumstances the stutterer's enunciation is perfect. It is evident, then, that it is no mere defect of articulation nor of co-ordination, for the muscles at times harmonize perfectly in their action.

Stuttering is mentioned by Hippocrates, Aristotle, and Galen, but in a somewhat indefinite way. We are told by Plutarch that Demosthenes had a difficulty of enunciation, which he overcame by declaiming as he walked uphill, and by holding pebbles in his mouth as he rehearsed his speeches. The latter plan has points of resemblance with modern devices, as we shall see; but it is not at all certain, from the account, whether the defect which it removed was really a stutter, or some form of stammer. At any rate, he adopted an excellent form of respiratory gymnastics, which are the foundation of most of the modern systems of treatment. During the Middle Ages writings on the subject appeared occasionally, imputing the trouble to malformation of the tongue, cerebral disease, etc., but no work of importance was done until the beginning of the present century.

Itard (1817) divided stuttering into two classes, congenital and accidental. Under the latter head he included speech defects due to cerebral lesion or organic disease of the tongue. He recommends beginning treatment early, and teaching the child slowly and carefully the pronunciation of a foreign language, dropping for a time his own. In this way he is taught, from the very first, to combine sounds properly, and to give prominence to the vowel sounds rather than to the consonants.

In 1825 Mrs. Leigh, of New York, discovered a method of treatment which was kept for a long time secret. She thought the trouble due to a faulty position of the tongue, which is spasmodically depressed during the attack. To overcome this, she taught her patients to voluntarily raise the tip of the tongue, and keep it in this position while speaking. Her results were at first surprisingly good and attracted much attention, as well throughout Europe as in this country.

M. Serres d'Alais (1829) published a more scientific résumé of the subject, in which he divided the cases into two classes:

1. Those due to a stiffness, as if tetanic in character, of the muscles of the voice and respiration.

2. Those due to a chorea of the muscles of articulation. He recommended in severe cases gymnastic movements of the arms while speaking; in light cases he considered it sufficient to pronounce the syllables in a short and brusque way, at the same time making the movements of articulation as extended as possible. He admitted that recovery is never quite complete, differing in this respect from most writers of the time, who, sceptical as to the statistics of others, claimed infallible results from their own particular method of treatment.

Arnolt (1830) ascribed the difficulty to spasmodic closure of the glottis. To overcome this he caused his patients to make a *u* sound between the words, so as to bind the consonant rather with the preceding than with the following vowel sound. In this way he threw the consonant into the background, as one does in singing.

At about this time Colombat, in France, attracted a good deal of attention by his brilliant success in treatment. He claimed to have cured one case in a single sitting of three hours, but, in a later edition of his work, he considerably modified this statement, and other authorities say the case relapsed several times In fact, so many tables of statistics have been compiled from the immediate results of treatment, without waiting to see whether relapse occurred, that they are almost entirely worthless. Colombat gives a classification of cases much like that of Serres d'Alais into:

1. Repetition of syllables due to convulsive movements of the tongue and lips, or labio-choreic form.

2. Tetanic stiffness of the muscles of respiration, or gutturo-tetanic form.

For the first form he recommends the use of a rhythmical movement of the thumb and index finger during speech, and an instrument for beating time, of his own invention, called the muthonome. If the case is complicated by gutturo-tetanic spasm, he adds "lingual and guttural gymnastics, which consist in taking a deep breath before difficult words and phrases, and bringing the tongue into the pharynx, at the same time raising the point well toward the velum palati." His method is, after all, only a combination of preceding ones, but seems to have been effectual in producing, for a time at least, very good results.

The year 1841 is unique in the annals of this affection. In that year operation was proposed, and hundreds of stutterers were operated on, but before the end of the year the surgeons themselves were convinced of the uselessness of operation. The idea was suggested to the mind of Dieffenbach, of Berlin, by the frequency with which stuttering and strabismus exist in the same patient, and occurred to him, he says, when a man asked, with a marked stutter, to be operated on for strabismus. The operation which he usually performed was section of the root of the tongue, sometimes with excision of a triangular piece throughout its entire length and breadth. This proceeding was based on the theory that stuttering is purely a local affection. At about the same time several other operations were invented, *e.g.*, cutting the hyoglossi, genioglossi, etc., varying with the different theories of the surgeons as to the cause of the trouble. At first, cases were reported as cured by each of these methods. Later, relapses were said to have occurred. Then several deaths were reported, and operation was soon, by common consent, abandoned as useless. Dieffenbach himself admitted the extreme danger of the proceeding. The deaths were the result of secondary hemorrhage and gangrene. The results attained immediately after operation seem to have been due to the impression on the nervous system of the patient, which wore off as soon as the effects of the operation subsided.

Since that time a good deal has been written on the subject of stuttering, largely by stutterers themselves, both in and out of the profession: by Guillaume in France, Merkel, Klencke, and Kussmaul in Germany, and Potter in America, and many others.

Guillaume lays especial stress on the disturbances of respiration.

Merkel thinks that the difficulty lies in combining a consonant with the following vowel sound. He locates the trouble, not in the articulation, but in the vocalizing apparatus, or, farther back still, in the nerve centres which govern that apparatus.

Bristowe likens stuttering to chorea.

Causation.—Among the many theories which have been propounded to account for the symptom under discussion, that which ascribes it to malformation or disease of the organs of articulation is one of the oldest, and one which held its ground longest. It is the foundation of all operative interference, and is readily disposed of. In many pronounced cases of stuttering the tongue and lips execute ordinary movements perfectly. No abnormality is noticed except during speech; and when organic trouble coexists, its removal does not entirely cure the affection. Any conceivable degree of deformity may exist and cause nothing but stammering, which is then proportional to the amount of the lesion.

Stuttering is not due to a faulty position of the tongue, as is shown by the constant relapses which occurred after treatment by Mrs. Leigh's method. It is true that in many cases the tongue is pressed against the floor of the mouth, and is affected with clonic spasm in this position. This is, however, not always the case, and when it exists it is a result, not the cause, of the malady.

The trouble is not a chorea of the muscles of articulation. The characteristic of choreic spasm is that it is irregular and jerky and occurs during rest. The spasm of stuttering occurs only during voluntary excitation of the speech mechanism. Again, chorea, when it affects the lips and tongue, causes marked stammering, never stuttering. Chorea of the speech centre, or coprolalia, causes a spasmodic ejaculation of words or phrases independently of volition, and the words are perfectly articulated.

That the trouble is due to confusion of ideas, or disproportion of words and ideas, is obviously false. Stuttering occurs in persons of every grade of mental power. The greatest disproportion between words and ideas occurs in acute mania, and leads, not to stuttering, but to a chaotic mixture of words and syllables. In most persons failure of ideas is marked by a drawl, not a stutter.

It is not due to a simple ataxia of the muscles used in speech. If it were, the patient could at once control the irregular movements by ceasing to speak. But when he does this, the spasm invariably persists for a short time. Again, stuttering is only occasional, and made worse when the patient's attention is directed to his speech; ataxia is constant, and is diminished by attention.

The theory that it is an inability to combine the consonant and vowel sounds is inadequate to explain the symptoms. The occasion of so combining them is often the proximate cause of an attack, somewhat as general convulsions are caused by teething or other peripheral irritation; but stuttering may occur on an attempt to utter a pure vowel sound entirely apart from a consonant.

In order to understand the phenomena presented, it will be necessary to review briefly the structure and physiology of that part of the motor speech centres which serves for the production of articulate sounds. The motor impulse travels from the motor speech centre in the left third frontal convolution, downward through the knee of the internal capsule, and reaches the medulla. The nerves carrying it here communicate with the articulo-respiratory centre. These nuclei lie close together, and constitute practically one collection of cells bound together by fibres running in every direction. Here, and possibly also in the cerebellum, is effected the exact degree of innervation of all the muscles of articulation, so as together to produce the vowel and consonant sounds and at the same time to approximate the vocal cords, and so regulate the respiration as to cause exactly the necessary amount of air to pass through the glottis. This exceedingly complex action is entirely apart from the conscious act of speech, and is only known to the sensorium through the intervention of the sensory nerves supplying the mucous membranes and deeper parts of the lips, tongue, and palate. The amount of innervation of each muscle is determined by lines of least resistance in the connecting fibres, which are formed as a result of repeated transmission of motor impulses. This whole system is probably under the influence of one or more controlling centres, which serve to check over-action, or the undue diffusion of nerve force.

Stuttering is a disturbance of this co-ordinating mechanism. It may be due to abnormal excitability of the primary system, or to weakness of the inhibiting centre. The result is an overaction of the muscles innervated, and transmission of the impulse to other muscles more or less distant, sometimes even to those of the arms and trunk; the attempts of the patient to overcome the spasm only serve to intensify it, until the controlling centre resumes its function or the patient ceases the effort to speak.

Several facts tend to show that the trouble is adynamic in origin—*e.g.*, the fact that patients usually stutter worst when tired; that persons sometimes stutter when exhausted, or during sickness, who do not otherwise; that stutterers are often, though not always, of weak or scrofulous constitution.

This disturbance of equilibrium between the centres is often the result of an inherited tendency. It may follow severe illness, fright, or any shock to the nervous system. In such cases the trouble may pass off when the depressing influence ceases, or may persist for a long time, or through life. In any case the intensity of the disturbance depends much on the treatment and surroundings of the patient, anything like ridicule or punishment aggravating it tenfold.

Occurrence.—Stuttering occurs in all ranks of society and in most nations. The Chinese are said to be exempt, on account of the peculiar intonation of their language. It affects men much oftener than women, although trustworthy statistics on this point are lacking. Some authorities have thought that women do not stutter; others place the proportion of women affected as high as thirty-five per cent. Kussmaul believes the fact to be due to the greater tact and delicacy of women.

Symptoms.—These vary much in point of severity and mode of sequence of the spasm. In lighter cases, which are fairly under control, when one of the explosive consonants is met with, the organs of articulation remain fixed in their closed position for a moment, there is slight choking and tremor of the facial muscles, an effort of the will is made, and the parts resume their functions.

In rather more severe cases there may be added a good deal of thickening and tremulous movement of the tongue and tonic spasm of the glottis. The breathing is then apt to be irregular, and the approximation of the vocal cords causes a crowing sound on inspiration, which is sometimes utilized for speech.

When the spasm occurs before speech has actually commenced, the trouble begins with tonic spasm of the glottis, there is tonic and clonic spasm of the tongue, lips, and face, and the diaphragm acts irregularly in its efforts to overcome the resistance at the rima glottidis.

In severe cases the attack may be brought on by any sounds, less frequently the open vowel sounds; the closure may be effected by the lips, tongue, or palate; the under jaw is set; there is marked tremor of the facial muscles, and sometimes even of the arms; the glottis may be closed so as almost or entirely to prevent respiration, or it may be opened at the same time that there is spasm of the respiratory muscles. In the latter case the lungs are emptied of air, and the patient must pause for a deep breath before he can proceed with his sentence. At the same time the face becomes flushed, the flow of saliva is increased, and the mental torture of the patient tends to prolong rather than cut short the attack.

Diagnosis.—The diagnosis is usually easy. In addition to the clinical features given above, the duration of the malady should be carefully ascertained. Its diagnostic features have already been considered.

The speech defect which occurs in paretic dementia may simulate stuttering quite closely.

In clergymen and other public speakers there sometimes occurs a difficulty in speaking, which may be mistaken for stuttering. It is one of the occupation neuroses, of which the type is writer's cramp, and is due to exhaustion of the co-ordinating mechanism of respiration. Some speakers entirely empty their lungs before taking breath; the action of the reflex mechanism is then kept too long in abeyance. When this is habitual, the centres become exhausted and fail to respond to the reflex stimulus. The trouble usually begins in the glottis, which fails to open on inspiration; a crowing sound is produced when the speaker takes breath; the diaphragm cannot be promptly filled for the next sentence. This may happen only toward the end of the discourse, when the speaker is tired, but may become so marked that any attempt to speak causes great distress, and rest is then an imperative necessity. This affection differs from stuttering by occurring comparatively late in life, not involving the muscles of articulation, and being rather of a paralytic than of a spastic nature. It ordinarily yields to rest and respiratory gymnastics.

Another rare affection, aphthongia, is probably allied to the preceding. Here the spasm occurs in the muscles supplied by the hypoglossal nerve, and is brought on by any attempt to speak, so that articulation is rendered impossible. In the few cases recorded the disease has been caused by emotion or fright. During the attack the jaws and tongue are fixed; the sterno-thyroid, sterno-hyoid, and thyro-hyoid muscles may be in a state of clonic spasm, which begins and ceases with the attempt to speak. The prognosis seems to be good. Too little is known of the disease to speak of its probable relation to stuttering. It may be distinguished by the character and history of the attacks.

Prognosis.—There is no doubt that sufferers from this affection may be aided by treatment, especially if the latter is vigorous and instituted early. The prognosis is better in non-hereditary cases, and in patients of strong will power. Almost all writers on the subject have a favorite method of treatment, especially those who are connected with an institute for voice-training, and claim a large percentage of cures. Investigation shows that in most cases relapse takes place after an even brilliant result. This should not discourage patients from effort, but it is necessary to bear in mind that only constant and long-continued exertion will overcome a vicious tendency fixed by habit. The difficulty tends to decrease with time, and many stutterers are able to master their defect at forty or fifty years of age. They are apt to ascribe this to some particular form of treatment, which they then ardently recommend

Treatment.—Too much stress cannot be laid on beginning treatment early. The child should be kept as much as possible from association with stutterers. It should be remembered that he is sensitive as well to sympathy as to blame for his malady, and as little notice should be taken of it as possible, except in connection with stated lessons. He should be taught, when he has an attack, to stop speaking at once until he has mastered it.

Breathing exercises are very important. They may be given, following Guillaume, by causing the patient to take a long breath, hold it for a moment, and then let it out slowly, with occasional stops, but without sound. He should especially be made to take a deep breath at frequent intervals, and never to speak with nearly empty lungs.

After breathing exercises have been continued for some time, the patient may proceed to the vowel sounds, first the most open one, *ä*, then *ā*, *ă*, *ē*, *ĕ*, *ō*, *ŏ*, and so on; then the aspirates, *hä*, *hā*, etc.; next the easier consonants in combination, *lä*, *lā*, *lē*, *lō*, *lū*, *mä*, *mā*, etc. Sentences may then be used in which the difficult sounds do not occur. Lastly, the explosives *dä*, *dā*, *bä*, *bā*, etc., may be tried. With all of these the patient should be taught to lay the stress on the vowel sounds, so as to avoid the slight over-action with the consonants, which is usually the beginning of the spasm. One must be sure that the pupil has mastered each of the above classes before he is permitted to go on to the next.

We have a mass of evidence from stutterers, in the profession and out of it, testifying to the efficacy of rhythmical movements accompanying speech. They serve a twofold purpose—they divert the patient's attention, and give his sentences something of a sing-song character. They are aids, but are in no sense curative. The thumb and fingers may be opened and closed, or any other movement made which is convenient to the patient. Somewhat the same effect is produced by elevating the tip of the tongue, as recommended by Mrs. Leigh, but it will be better, in most cases, to draw the patient's attention to a more distant part of his body.

Hypnotism has been tried of late as an aid in treatment. If it is ever of use as an educational measure it should be so here. Good results are claimed for it. Whether they will prove to be permanent, and without accompanying injury to the patient, it is possibly too early to judge.

Drugs are of little value. Stimulants should be used moderately, if at all. Scrofulous and anæmic tendencies should be corrected, and the patients should be kept in good general health by exercise, cold sponging, and like measures.

The question is often asked, whether it is possible for an adult to master his defect without assistance from a teacher. That is entirely an individual matter. Some men have perseverance enough to educate themselves in this as in other respects. Proper teaching, however, saves much time and disappointment.

STARCH.—(*Amylum*, U. S. P.) ($C_6H_{10}O_5$, or multiple). "The fecula of the seed of *Zea Mays* L. (fam. *Gramineæ*)." U. S. P. There appears to be no special reason why the Pharmacopœia should thus restrict its requirements to corn-starch, except that this variety is cheap and abundant

Fig. 4473.—Section of Seed of Vetch, *Vicia sativa* Linn., showing rounded granules of starch in cells otherwise filled with granular nitrogenous substance. × 170.

and readily defined and described. Our account of starch, therefore, will apply to the entire class, and will be followed by the differential characters of the more important varieties.

Starch is the ordinary form of reserve carbohydrate nutriment in plants, at least in most of those of the higher classes, and in many of those of the lower classes. It may be reserved for but a brief period, at the point where it is produced, or it may, after production, be changed into diffusible forms and transported to special storage reservoirs, where it is again transformed into starch, and may remain for months or even for years. For example, being produced only under the influence of light, it may be consumed during the succeeding hours of darkness, or, upon the other hand, it may be transported to the bulb or tuber of a desert plant, which may exist dormant in the sand for several years, consuming this starch supply upon the recurrence of a period of activity. In the most highly developed and largest family of plants, the *Compositæ*, and in some others, inulin, a related compound, altogether replaces starch as a reserve food. The amount of starch present in vegetable tissues is often very great, being about seventy per cent. in dried potato, and about the same in corn meal and wheat flour. With the exception of some rare cases in which special forms are found, starch occurs in peculiar grains, which are free in the cell cavity. It originates in a small colorless body known as the amylogenic body, upon which the starch gathers in layers, the central body becoming the *nucleus*, and being located in the grain at the *hilum*. The numerous layers of the grain are discernible under the microscope by their different degrees of refraction, due apparently to different amounts of water, as they disappear under the effect of drying heat. The grains may exist singly, or coherent in masses containing a variable number. The limits of this numerical variation are often fairly constant in a given plant, and may thus be utilized as a characteristic. This cohesion often produces peculiar forms of the grains, which forms also become characteristic. Even if this is not the case, the form of the grains in a given plant is usually characteristic, as is the position of the hilum. The larger grains usually become ruptured or fissured at the hilum. This fissure may be simple or in various ways compound, and the forms so resulting are also characteristic. In all starches in the living plant there must be small grains of various sizes in process of formation, but the largest of them usually fall fairly well within certain limits, so that

Fig. 4477.—Maize Starch.

the extreme limits of a given variety are of diagnostic value. Although single starch grains are colorless and semitransparent, masses of them are pure white.

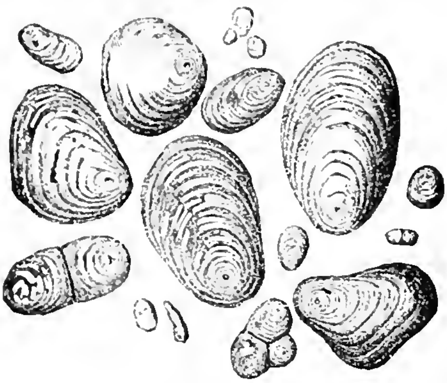

FIG. 4478. Potato Starch.

Starch powder is very fine and smooth, but the ultimate grains are hard and gritty. They are very hygroscopic.

Starch has no odor, but a peculiar, though slight, farinaceous taste. The grain consists of two substances, *granulose*, which is colored blue by iodine, and another substance very similar to cellulose, colored pale yellow by iodine. Starch is insoluble in water and alcohol. Several substances are often spoken of as solvents of starch, but they all apparently change it into some other compound before the solution takes place. Water, under the influence of heat, converts it into hydrated starch, a transparent, jelly-like mass, which is then soluble in water. Alkali hydrates of a strength of more than five per cent. similarly dissolve it. Both these solutions are then precipitated by lime water, lead acetate, tannin, and some other reagents. Diastase, the principal enzyme which naturally exists with starch, is the agent which in the plant converts it into sugar, suitable for immediate use as food. The same agent can be made to perform this office artificially, as can dilute acids under the influence of heat, and as is done by the natural processes of digestion within the animal body. From the above-mentioned characters of starch, it is seen that it can readily be obtained by grinding finely any cellular structure which contains it, washing out with cold water and filtering or allowing to settle. It is also seen that, besides the interest which centres in starch for its own value, the characteristics of the starches contained in different plants, and more especially in drugs, may be utilized in the identification of the latter, in powdered form, as well as in the detection of adulterations.

VARIETIES.—The only certain means of determining from what source a given specimen of starch has been derived is to examine it microscopically, when the size, shape, markings, and other visible peculiarities of the granules will generally suffice to make it certain. The accompanying illustrations of the commoner kinds are magnified uniformly three hundred and fifty diameters.

1. *Wheat Starch* (from various species and varieties of *Triticum* L. [fam. *Gramineæ*]) (Fig. 4476). In irregular, angular masses, which are easily reduced to powder; under the microscope appearing as granules, mostly very minute, *more or less lenticular in form, and indistinctly concentrically striated.* The granules average about 0.050 mm. in diameter.

FIG. 4481.—Tapioca.

2. *Maize*, or *Corn Starch* (defined above, Fig. 4477), is smaller than the preceding, about 0.030 mm. in diameter, of polyhedral form, with central hilum.

3. *Rice Starch* (from *Oryza sativa* L. [fam. *Gramineæ*]) resembles maize starch, but is very much smaller.

4. *Potato Starch* (from *Solanum tuberosum* L. [Fam. *Solanaceæ*], Fig. 4478) consists of two classes of granules mingled together—fine spherical ones, from 0.01 to 0.03 mm. in diameter, and large ovoid ones with very eccentric hilums and very distinct *rugæ*, recalling oyster or clam shells, from 0.14 to 0.18 mm. long.

5. *Arrow-root* (from *Maranta arundinacea* L. [fam. *Marantaceæ*] Fig. 4479) is finer than potato starch, which it somewhat resembles; the granules are more spherical, with blunter, thicker ends, very distinct eccentric fissures, and less distinct *rugæ*. Canna starch, a variety of arrow-root, has enormous granules, nearly twice as large as those of potato. Neither of these varieties has the small forms of that from potato.

FIG. 4482.—Oat Starch.

6. *Sago* (chiefly from several species of *Metroxylon* Rottb. [fam. *Sabalaceæ*] Fig. 4480) has medium-sized (0.04–0.07 mm.), oblong, rather irregular, often faceted, sometimes shoe-shaped granules, with eccentric hilum and fairly distinct *rugæ*. The sago of commerce is often half-cooked, with many of the granules destroyed.

7. *Tapioca* (Fig. 4481) has spherical, medium-sized granules, with large facets; commercial tapioca is also partly cooked. (See also separate article on *Tapioca*).

Besides the above are the starches of numerous familiar grains and roots, which are not separated for sale or use, but which are of interest in detecting adulterations, mixtures, etc., or in identifying the powders of drugs. The accompanying cuts of oat and turmeric starches will serve as illustrations of this large class.

FIG. 4483.—Turmeric Starch.

Medical and Surgical Uses of Starch.—This substance can in no sense be called a medicine, as it is absolutely without physiological action. It is the type of crude carbonaceous or non-nitrogenous food, and its conversion into sugar in the mouth and intestine is one of the elementary facts of digestive physiology. As a toilet powder the finer varieties—rice and corn starches—are in universal use, and one or other of these is the foundation of most of the proprietary powders.

Boiled starch, and especially the flours of starchy substances, are frequently used as poultices, but they are not so convenient and suitable as the mucilaginous flours of linseed and slippery elm.

Starch mucilage is occasionally used for immovable bandages, but it is less adhesive and less suitable for this purpose than flour paste, glue, dextrin, silicate of potash, or plaster of Paris. One part dissolved glue, as prepared for cabinet-makers' use, and two or three of starch mucilage, a little thinner than the laundress uses it, mixed and applied hot, make a most excellent combination for such bandages—light, very stiff, and agreeable in color.

The only official preparation of starch is the Glycerite (*Glyceritum Amyli*, ten parts of starch dissolved in ninety of hot glycerin). This is a permanent translucent jelly, useful in moistening pill masses, for emulsions and similar purposes. Iodized Starch (*Amylum Iodatum*, formerly official) is rather a preparation of iodine. It is made by triturating five parts of iodine with ninety-five of starch, with the aid of a little water. It is a blue-black powder, and a suitable preparation to administer for free iodine if it is desired to give that drug internally.

STARK MINERAL SPRING.—New London County, Connecticut.

Post-Office.—Bozrah. Visitors accommodated in private families.

Location.—Three miles from Yantic, on the Central Vermont Railroad.

The waters of this spring issue from a rocky hillside on the farm of Mr. Everett W. Stark, at an altitude of about 1,000 feet above the sea-level. Its history has been known to a few old families in the neighborhood since the first settlement of the country, and dates back to a time when all accurate record is lost in the obscurity of tradition. There seems to be no doubt, however, that its waters were used for medicinal purposes by the Indians long before the region was known to the European settlers. The surroundings of the spring are very charming during the summer months, and an increasing number of visitors are attracted to the spot every year. The flow of water is about three gallons per minute, and its temperature about 40° F. The following analysis was made by Prof. S. W. Johnson, of Yale University, in 1880:

One United States gallon contains (solids): Sodium chloride, gr. 0.33; sodium sulphate, gr. 0.18; sodium bicarbonate, gr. 0.30; potassium bicarbonate, gr. 0.10; calcium bicarbonate, gr. 1.23; magnesium bicarbonate, gr. 0.33; iron bicarbonate, gr. 0.06; silicic acid, gr. 0.85. Total, 3.38 grains.

The analysis shows the spring to be but feebly mineralized. The waters, however, have been considered useful in some of the functional disorders of the liver, kidneys, and bladder. It is a good table water.

James K. Crook.

STARVATION; FASTING.—The latter term signifies the partial or complete abstinence from the normal quantity of food. It may include the absence of both liquid and solid food, or of the latter while water only is ingested. This process, when carried out to a fatal result, constitutes starvation. The somewhat cumbersome word inanitiation has been used to refer to the condition of the animal which is progressing toward inanition.

The fasting animal carries on its vital functions, and whatever muscular action it may perform, not, as normally, by the conversion of food supplied by its ingesta, but at the expense of its own tissues. The physiology of fasting, which has not as yet been thoroughly elucidated, may be studied to best advantage by experiments upon the lower animals, for, in addition to the ability to control conditions, we thus eliminate psychical influences, and those other disorders which complicate the problem in those instances in which human beings undergo starvation while under the possibility of medical observation.

Loss of Weight.—This is the earliest and most obvious symptom of the fasting animal. The daily loss is not, however, constant. It is greatest during the first day of the fast. Then it diminishes, and after a few days becomes a nearly constant quantity until the last days of life, when it again increases, but not usually to the amount of the first day. The proportional daily loss—that is, the loss in grams per kilogram of the animal's weight—is readily obtained from the absolute daily loss, the weight of the animal being known. But it must be remembered that the latter factor must be ascertained for each day in question, and must not be taken to be the original weight of the animal. Thus, for instance, a constant total daily loss of 200 gm. in an animal originally weighing 4 kgm. would at first mean a proportional daily loss of 50 gm. per kilogram, but would, with every successive day, represent a larger proportional loss. The mean daily loss may be obtained by dividing the total loss in a given number of days by that number; but of course it must be remembered, as said above, that the actual daily loss is not so constant. A mean daily proportional loss can, in the same way, be computed.

This figure varies with the different species of the animal kingdom. It is, as a rule, higher for the smaller animals. The horse loses less daily per kilogram than the dog, and the dog less than the cat. This fact is in accord with the greater nutritive activity of the small animals. That this greater activity is not due to increased heat production is shown by the fact that these small animals consume more oxygen per unit of time and weight, even when placed in a medium of the temperature of their bodies. An adult animal loses less daily per kilogram than a young animal of the same species. The daily mean proportional loss varies widely, being ten per cent. of the weight in the young turtle, and only 0.7 per cent. in the horse and dog.

What proportion of the body weight can an animal lose before succumbing to inanition? If we know this, and if the total weight loss during a period of starvation bore a constant ratio to the original body weight, we could easily compute, knowing the daily proportional loss, the length of time that life could last. It is, however, only true that the amount of the daily proportional loss, and the number of days that life can endure, are inversely proportional. Chossat stated that the total proportional weight-loss of an animal dying of inanition was forty per cent. of the initial weight. But further experiments have shown that a fat animal may lose fifty per cent. of its weight, while a lean one can lose only thirty-five per cent. Young animals in a growing stage have been observed to lose only thirty per cent. before they succumbed. Thus we have two reasons why young animals can endure fasting but a short time, namely, that their daily proportional loss is a maximum, and the total proportional loss of which they are capable a minimum. The reason of this last-mentioned fact seems to be that the demands of the growing organism have used up force which might otherwise be applied to the nutritive reserve of the body.

Organs and tissues.	Loss in grams per 100 gm. of organ.		Loss in grams of each organ per 100 gm. of loss of whole animal.
	Fresh.	Dry.	
Osseous system	13.9	13.9	5.4
Muscular tissue	30.5	30.2	42.2
Liver	53.7	56.6	4.8
Kidneys	25.9	21.3	.6
Spleen	16.7	63.1	.6
Pancreas	17.0	17.0	.1
Lungs	17.7	18.0	.3
Heart	2.6	2.6	.02
Brain and cord	3.2	.0	.1
Fat	97.0	97.0	26.2
Blood	27.0	17.6	3.7

The proportion of the entire weight-loss which falls upon the different structures of the body varies somewhat with different experimenters. Voit found that a rather lean cat, which died on the thirteenth day of its fast, lost 734 gm. of solid material, of which 248.8 were fat and 118.2 muscle. The table on page 441 shows the most important facts of the loss of several of the organs in proportion to their original weight, and in proportion to the entire weight-loss of the animal.

It should be said that Bidder and Schmidt, whose experiments were made upon a very fat cat, found that the muscular system lost sixty-seven per cent. of its original weight, the brain and cord 37.6 per cent., the blood ninety-four per cent., and the fat eighty per cent. Some of these discrepancies seem irreconcilable. Others, like the fat-loss, depend on different conditions in the respective animals. That of the latter observers had so much adipose tissue that, though he lived seventeen days, he had consumed only eighty per cent. of his fat, while the cat experimented on by Voit had used up ninety-seven per cent. of his in thirteen days.

What is substantially agreed is that the fatty tissue is the heaviest sufferer in the fasting animal; that certain glandular organs, principally those whose metabolic activity is greatest, come next, the average for all these being greater than for the body at large. The loss of the voluntary muscular system is about in the same proportion as that of the whole body, as is also that of the digestive tube (thirty per cent.—Voit). Those structures which are most essential to the life of the organism are spared longest. The heart muscle and the central nervous system lose practically nothing, and though their metabolic activity is high, they are sustained at the expense of less important tissues.

Temperature.—The experiments of Chossat, upon pigeons, show a remarkable and continuous effect upon temperature from the beginning to the end of a period of starvation. This shows itself at first in an increase of the diurnal range, owing to a lowering of the midnight temperature. Whereas, in the healthy pigeon, the daily oscillation is only 0.76° C. (from 42.22° at noon to 41.48° at midnight), in the fasting animal the mean noon temperature (prior to the last day) was 41.70°, and the mean midnight temperature 38.42°, giving an average diurnal range of 3.28° (four times as great as normal). The average loss of temperature at noon was only 0.52°, while that at midnight was 3.06°. That is to say, the loss of temperature at midnight was six times as great as at noon. Moreover, the diminution of temperature was progressive from the beginning to the end, as was also the amount of the daily oscillation. This latter was 1.9° the first day, and 4.3° the last day but one. The mean daily refrigeration during this period was 0.3°. As the animal grows weaker, the period of minimum (midnight) temperature begins earlier and lasts longer.

On the final day of starvation there is a great exaggeration in degree and in duration of this midnight refrigeration. Chossat gives it as a mean, in a number of pigeons, as 14°. In other words, the reduction of the animal heat is forty-seven times as great on the last day of life as on the average of the previous days.

This final plunge of the temperature is observed in all cases of starvation, and there seems little reason to doubt that it is the immediate cause of the fatal result. In the mammalia there was not that regular daily loss of heat that was observed in the pigeons. The temperature fell for the first day or two, but then nearly regained the normal, and so remained until the last day, when it rapidly sank. Chossat found that when this fall occurred, the resulting torpor, the precursor of death, could be dispelled by raising the temperature of the surrounding medium, and that sufficient vitality was thus imparted to allow of the taking of food and consequent perfect restoration of the animals. The nearly complete maintenance of temperature of warm-blooded animals for several successive days does not prove that the heat production was equal to the normal, for there is probably a lessening of the heat expenditure. Senator found that with dogs, on the second day of the fast, when the rectal temperature was not sensibly lowered, the heat production was nevertheless diminished about ten per cent.

Temperature studies in fasting men, of course, have been rare. Jürgensen found that in a healthy man, fasting for sixty-two hours, the rectal temperature, taken every ten minutes during the first thirty-eight hours, showed a slight prolongation of the period of diurnal minimum, with but very slight reduction (0.1°–0.2°) in the reading of the minimal temperature. But after that time there was a prolongation of the period of the maximal temperature, which Jürgensen accounted for by supposing that the substance of the consumed body set free more heat than the materials metabolized under ordinary circumstances.

Respiration.—The frequency of the respirations diminishes during fasting to four-fifths, or during the last day even to three-fifths, of the normal rate. Sometimes, however, just before death the breathing becomes hurried, shallow, and panting. The quantity of carbonic acid exhaled, which normally exceeds that of the oxygen taken in the proportion of about five pounds of carbonic oxide to four pounds of oxygen, becomes relatively smaller during fasting, and may even be absolutely less than the oxygen absorbed.

Circulation.—No very constant effects have been noted in this connection further than a general tendency to increase in the rate of the pulse accompanying exhaustion. One observer (Strelzoff) noted an increase in the blood pressure, which he ascribes to an atrophy and obliteration of a large number of the capillaries. Though this latter event occurs in the stomach and small intestine, and perhaps in other parts of the body, it probably is not sufficient to cause any general rise of blood pressure. The mass of the blood proportionally to the total weight, as above indicated, seems not to suffer very great reduction. Panum found no diminution in the number of blood corpuscles when the animal (a dog) was allowed all the water desired. On the other hand, Malassez found that in the guinea-pig the corpuscles were reduced on the fifth day from 4,156,000 per cubic millimetre to 3,444,000. In a chicken he observed a reduction, in an equal time, from 3,380,000 to 2,912,000. The diminution in both the last cases fell chiefly upon the latter days of the fast.

The density of the blood was found by Frerichs and others to diminish during a fast. In a dog, in which before the fast it was 1058.09, on the fourth day of the fast it was 1051.11, and on the twelfth 1037.69. On the other hand, in Voit's cat the density of the blood increased.

Urinary Secretion.—The amount of the urine during the first day of the fast is not usually affected. After that time, however, it gradually grows less and less. The specific gravity has been found during this period to range between 1.025 and 1.034.

The urea diminishes in the carnivora with every successive day of fasting, but never entirely ceases. The extent of the diminution depends upon the richness of the food in nitrogenous elements prior to the fast. The herbivora, on the other hand, which during a fast become carnivora, experience at that time a change in the character of the urine, which becomes denser, higher-colored, acid, and richer in urea. At the end of life the urea diminishes rapidly. In guinea-pigs it has been found that the urine taken from the bladder after death had only one-eighth as much urea as that passed on the preceding day.

The urea forming a measure of the decomposition of nitrogenous materials in the body, and nitrogenous ingesta (with all other) having been stopped in the fasting animal, the daily secretion of urea affords a means of estimating the amount of nitrogenous matter consumed each day of the fast. Physiologists have been divided over the question of a *luxus consumption*, a term applied by Bidder and Schmidt to the metabolism of certain surplus proteid material which, though inside the body, did not form a component part of any of its tissues, but constituted a kind of reservoir of force upon which the organism could draw. Not to enter upon this question, however, we will simply say that it is found that the excretion of urea bears no fixed proportion, at any period of the fast, to the total weight of the animal, although after the first three or four days it tends to a uniformity for several days. If the animal possesses an abundance of fat there is a smaller consumption of proteids during fasting. This diminution of the urea is very noticeable in animals that have been freely fed, previously to beginning the fast, on fatty food. In the lean cat of Voit, already referred to, the urea was less for several days than in the animal of Bidder and Schmidt; but at the end of life (twelfth and thirteenth days) there was a rise of fifty per cent. in the urea excreted over that of the previous day, while the other animal showed no such increase even up to its death, on the seventeenth day. The former animal was found at the autopsy to have used up all his fat tissues, and the final rise in the urea was due to the metabolism falling entirely upon albuminoid material.

Of the other constituents of the urine the phosphates and sulphates undergo a diminution parallel to that of the urea. The chlorides also diminish, but more rapidly from the first. Albumin has been noted in some cases, but is not constant.

FÆCES.—On the first day of the fasting there is usually an evacuation from the bowels, the fæcal matter containing the residue from the preceding alimentation. After this the fæces are scanty, often none being passed for many days. They consist, after the second day, almost entirely of bile. Scarcely any gastric or pancreatic juice is formed. Sometimes a colliquative diarrhœa sets in on the last day of life.

In the foregoing remarks we have had reference to a total deprivation, for a longer or shorter period of time, of food. It is now necessary to examine briefly the effects when, although a completely nutritious diet is wanting, certain partial nutriments are allowed. As is well known, the proteid foods, though uneconomical in the quantity required, and in the tax imposed on the digestive organs, are of themselves competent to support life. Not so, however, with the non-proteid albuminoids, gelatin and chondrin, or the non-nitrogenous fats and sugars. Yet all these classes of food will spare the destruction of a certain amount of the albuminoid matters of the body and thereby prolong life. Gelatin is the most effective of these palliatives of starvation. Voit estimates that 100 gm. of dry gelatin economize 50 gm. of dry albumin. If fat be given with plenty of water, not only some of the fat tissue of the animal is spared, but also some of the albuminoid, and there is a slight increase in the carbonic-acid elimination over that observed in an absolute fast. Sugar also (if water be allowed) prolongs life, and under its administration the carbonic-acid elimination is greater than when fat is allowed.

We come now to the influence exerted by the allowance or withholding of water upon starving animals.

WATER ALLOWED AND SOLIDS WITHHELD.—The most important fact in this connection is that the administration of a moderate amount of water materially diminishes the loss of body weight and prolongs life to a corresponding degree. The elimination by the kidneys, and especially that by the lungs and skin, is increased by the drinking of water, but not to an extent equal to the water consumed. There is also less urea excreted when water is drunk.

Contrary, however, to what might perhaps be expected from what has just been said, the fasting animal requires a less quantity of water than the one which has plenty of food. The reason of this is that a considerable quantity of water is set free and put at the disposal of the organism by the destruction of tissue. Muscular substance contains 3.15 parts of water for each part of dry substance. In a dog experimented upon by Pettenkofer and Voit there was a loss of 175 gm. of albuminoid matter. This would set free 551.25 gm. of water. The water eliminated was found to be, as a matter of fact, less than this amount, being only about 506.1 gm., and in this case the animal, which was allowed to drink freely, took only 33 gm. The ingestion of water, then, while postponing the fatal result of a fast, produces no important change in the mode of death from that which occurs in simple inanition.

SOLIDS ALLOWED AND WATER WITHHELD.—When an animal is deprived entirely of water and of foods containing any considerable amount of moisture, starvation takes place almost as it does when solids also are withheld, for the animal soon ceases to eat. Two pigeons on which this experiment was tried by C. Falck and Scheffer gave as a mean the following figures: At first, being given enough water and wheat to maintain a uniform weight, they took per 1,000 gm of body weight, 103 gm. of water, and 85.5 gm. of wheat, a total of 188.5 gm., against which their total excreta were 187 gm. For the next four days water was withheld and wheat allowed *ad libitum*. Of the latter they took only 25.5 gm. per day, and their total daily excreta weighed 79.5 gm. Again, for eight days they received all the water and wheat they wished. This amounted in the first day to 442 gm. (342 of water and 80 of wheat). The excreta on this day were 180.5 gm. The average total ingestion for the first four days was 248.5 gm. (water 148.5 gm., wheat 100 gm.), the excreta 201 gm. On the next four days the ingesta were 176 gm. (water 91 gm., wheat 85 gm.); the excreta 176 gm. They had thus regained their former nutritional equilibrium. They were then again deprived of water until their death, which happened on the thirteenth day. The ingestion of wheat fell to 19 gm., and the excreta were 56 gm.

The mean daily loss of weight in pigeons so treated is from three and a half to five per cent. of their original weight, and the duration of life from nine to thirteen days. The total loss is from thirty-five to forty-nine per cent.—not materially different from what occurs where solids are withheld

DURATION OF LIFE DURING FAST.—As has been seen above, this has wide variations, depending as it does upon many factors, as the temperature of the surrounding medium, the quantity of fat possessed by the animal, etc. Perhaps an average would be from eight to ten days, during which the animal loses say forty per cent. of his weight. But, as we shall see in speaking of fasting in the human subject, this length of time may be enormously exceeded, as indeed it frequently is, in animals. In the classical case of the fasting pig, the imprisoned animal, which was enormously fat, was released alive at the end of one hundred and sixty days, having fallen away in weight from one hundred and sixty pounds to forty pounds.

In Man.—Inanition in man is usually more or less incomplete, but in a partial form it is not very uncommon. The insane frequently refuse food, and inanition may become quite advanced before the patients are put into an asylum, where, of course, they are fed, if necessary, forcibly. One such case is reported where a young man took nothing but water flavored with orange juice for sixty-one days. At that time he was seen by a physician and induced to eat, but, perhaps through injudicious treatment, he died on the eleventh day afterward.

Hysterical patients are particularly given to fasting, and reports of such cases often get into the daily press. Critical investigation usually develops the fact that there has been a good deal of deception of the attendants; but it is undeniable that such patients do subsist for long periods on an incredibly small amount of nutriment. In one notable case investigated by Charcot, the urine and the vomitus showed, on a most careful analysis, that the daily excretion of urea was only 5 gm. In a man, during complete abstinence, it was found to be not less than 10 or 12 gm. Many instances are on record in which hysterical women have dropped off one article of food after another, and have finally reached a point when, under perhaps one-tenth the normal amount of food, they pass a merely vegetative existence, lying on the back, obstinately constipated, with dry, rough skin, saying nothing, and, perhaps, only by a turn of the eye after a moving attendant, showing any appreciation of their surroundings. If they have practised deception they will sometimes, when put under strict surveillance, die of inanition without taking food. In the case of the so-called "Welsh fasting girl," who was reported to have lived without food of any kind for weeks, death occurred in eight days after she was placed under strict watch.

Inanition sometimes declares itself during the period of convalescence from acute fevers. There has been a large amount of tissue waste, with perhaps a small amount of nutriment taken. The importance of maintaining the nutrition in fevers is better recognized now than formerly, and probably extreme inanition is correspondingly rarer. But when the amount of food supplied has for some time been inadequate to the combustion maintained, we may expect to find the convalescence impaired by some of the symptoms of inanition.

The effect of starvation on the blood is temporarily to increase the number of red cells. This is apparent rather than real, and is due to a concentration of the blood. It is most marked in proportion as the *fluid* ingesta are withdrawn. In more advanced stages of starvation some deformity of the corpuscles may be expected, and a true anæmia.

Patients suffering from stricture of the œsophagus and from cancerous affections causing obstruction of the upper alimentary tract, sometimes die of inanition, though the recent development of the surgery of the stomach has much diminished the frequency of that event. Still, inanition plays a part in the symptomatology of many cases of cancerous disease, its effects being usually associated more or less indistinguishably with those of cachexia. In a case reported a few years since in *The Lancet* (November 27th, 1880), a patient having an œsophageal stricture was for ten months able to take nothing but milk. During this time he fell away in weight from one hundred and twenty to sixty pounds. For the next seven months he could swallow neither fluids nor solids, and was kept alive by rectal alimentation. He was able to walk about and his intellect remained unimpaired till three days before his death. At death his weight was forty pounds.

The new born are subject to a form of inanition due to incapacity to digest and assimilate the food ingested. Here a diarrhœa frequently replaces the constipation which, as we have seen, is a usual attendant of starvation. There is progressive emaciation, which may increase to the extent of thirty or even forty per cent. of the original weight. The skin wrinkles and the features take on an old look. The skin becomes inflamed from the contact of irritating discharges or from pressure. Often pustules of ecthyma appear. The chest is deformed; there is a sinking just above the epigastrium, while the xiphoid cartilage is pressed forward by the liver. The bones of the cranium overlap at the sutures and the fontanel is depressed. The belly is flattened; the stools are fetid. A peculiar odor, almost pathognomonic of starvation, exhales from the mouth and from the skin. The appetite at first is ravenous and the child calls for the breast constantly; later the appetite fails. The pulse and temperature lower progressively as the inanition increases; occasional transient elevations of temperature may, however, occur. The weight loss averages, in a child of 3 kgm., perhaps 100 gm. daily, and the duration of life may be eight or nine days. There is some reason to believe that robust infants succumb to inanition more quickly than weaker ones, perhaps because the latter require a less amount of force-production for their daily needs.

Clinical Observations of Simple Fasting in the Human Subject.—Few experiments, naturally, have been made upon human beings, and such as have been possible from the willingness of individuals to subject themselves to deprivation of food, have, unfortunately, been almost entirely devoid of scientific value. One is alluded to above under the subject of temperature. In the summer of 1880, a man named Tanner accomplished, as was claimed, a fast of forty days in New York. For the first two weeks he was not watched by any regular physician, but after that time one or more physicians remained with him constantly, and there seems little reason to doubt that he did actually keep the fast as represented, though there was an unfortunate lack of scientific observation of the phenomena presented. It being warm weather, there was comparatively little demand for heat-production. At the sixteenth day the man began to drink water, which was attended with marked improvement in his condition. The total loss of weight was thirty-two pounds. Toward the latter part of the time there was considerable nausea, ending in vomiting of biliary matter, mucus, epithelium, and a few blood corpuscles. There were very troublesome tympanites and obstipation after the first day. There was mental irritability, but no delirium. During the first part of the time he walked about and rode out daily, but later spent much of his time lying on a cot covered with blankets. One estimate of the urea gave on the first day 29 gm., on the fifth day 18 gm., on the eighteenth day 14 gm.

Famine and siege, which in years past have carried off multitudes of human beings by starvation, are no longer, it is to be hoped, capable of causing such destruction, at least in civilized countries. Shipwreck, however, remains as a not infrequent cause of starvation, under varying conditions as to heat, moisture, etc. Medical observations are not wanting upon the condition of men reclaimed at various degrees of inanition. The members of the Lady Franklin Bay expedition, under command of Lieutenant Greely, passed the winter of 1883–84 at latitude 78° 45′ N., longitude 74° 15′ W. From November 1st to March 1st, their daily ration was 14.88 ounces of solid food, the regular army ration being forty-six ounces. From March 1st to May 12th, the daily ration was ten ounces of bread and meat, with one to three ounces of shrimps. From May 12th to June 22d, there was no food but a few shrimps, reindeer moss, and black lichen scraped from the rocks. There was water, brackish in quality. The temperature of the surrounding medium was 5° to 10° F. There was no artificial warmth. The men, in general, slept much of the time (sixteen to eighteen hours daily), approximating a condition of hibernation. There was not much pain, even after going several days without food. It was only after the ingestion of food that the craving became great. Constipation was excessive; the intervals between the stools were eight to ten and even sixteen days. The men were obliged to dig out the hardened fæces with their fingers—the abdominal muscles being too weak to extrude them—and often fainted after evacuating the bowels. The deaths occurred seemingly from pericardial dropsy. There was œdema of the feet and face, then a short spasm of præcordial pain, and a slight general convulsion followed by death. The party consisted of twenty-five men; one died in January, of scurvy; sixteen died between March 1st and June 22d, when the survivors were rescued. The medical report showed the condition at that time to be as follows. (The report of one is given which is closely representative of all.) The patient fainted and vomited on first being removed. A sickly, offensive odor, as of stale urine, was emitted from the body, which was greatly emaciated, with skin hanging from the limbs in flaps. Weight one hundred and twenty pounds, the normal weight being one hundred and sixty-eight. Mind excitable and irritable, at times almost irrational. Loss of memory, attended later by amnesic aphasia. At first very talkative. No pain. Tongue dry and cracked, abdomen empty, and lying almost in contact with vertebral column; had had no stool for six days; ravenously hungry. Pulse 52, soft, compressible. Blowing murmur over base of heart in systole. Respirations twelve per minute. Temperature (under tongue) 97.2° F. No specimen of urine obtainable. Inability to move or stand without support. No sleep. Soreness and pain were felt in the muscles.

In the next few days there were alvine dejections, small, dark, and highly offensive, and showing diminution of bile. The skin became jaundiced for several days. The urine, normal in amount, was highly albuminous, and so continued for several days. No casts. Examination of the blood showed marked increase of white corpuscles (one to twenty red). The red corpuscles showed little tendency to cohere or to run into rouleaux. They lacked their distinctive biconcave disc shape. On the third day there were three or four hours of natural sleep. The pulse and temperature gradually rose. The anæmic murmurs continued for some time, as did the albuminuria. After a week the patient had gained nine and a half pounds, and was able to sit up. The appetite was still voracious. The mental condition was tranquil, and the amnesic aphasia disappearing. In six weeks the normal weight had been regained.

The *diagnosis* of inanition admits of no doubt except in cases in which it is complicated with other conditions. Yet it is just here that the diagnosis is sometimes of most importance, as, for instance, in the convalescence from acute fevers, where the success of the treatment depends on recognition of this element. It is first important to bear in mind that inanition is liable to occur whenever the supply of nutrient matter to the body has been interrupted.

In infants, as has often been remarked, most of the symptoms of inflammatory disease of the meninges may show themselves as the result of simple starvation. In fever convalescents there is sometimes delirium with headache, dimness of sight, and hallucinations. This condition has been mistaken for meningitis. But the headache in inanition is usually less severe, and the delirium, which probably corresponds to a condition of cerebral anæmia, is generally, though not always, of a calmer type. Still the hallucinations which result from it may lead to suicidal or homicidal attempts. One important point is, that the temperature is usually normal or subnormal, while in most other forms of delirium, save in light cases due to alcohol, it is elevated. The diagnosis of delirium due to inanition depends not so much on any peculiarity in the character of the delirium as upon the complexus of symptoms, the opportunity for starvation to have occurred, and the low temperature.

Sometimes vomiting sets in during inanition, a fact which should be borne in mind, in order that there may be no cessation of the nourishment on account of a misapprehension as to the nature of the vomiting. The food must be made as easy of digestion as possible, and, if it is rejected, rectal alimentation must be used as a temporary expedient. There is nothing in the character of the vomiting which is distinctive evidence of its source being in starvation. But, as with the more common symptoms just referred to, its nature must be diagnosticated from the other circumstances. Of course, vomiting may itself be the cause of inanition in cases of structural or functional disease of the stomach, but here we shall have a history of vomiting having preceded the excessive emaciation, instead of having followed it.

TREATMENT.—Much care is required, in the dietetic treatment of persons who have been subjected to starvation, that the nourishment be given in small quantities, and that the ravenous appetite of the patient be not followed as an indication of the amount of food required. In extreme cases some stimulant is often required at first on account of the great reduction of temperature; external heat should be freely applied. Meat seems to be the article best adapted to the resumption of long suspended nutrition. Scraped raw beef is one of the most valuable foods, and should be given in teaspoonful doses, flavored, every hour or half-hour. The fluid preparations of beef are also very useful. Milk may be given in alternation with these. From these beginnings the diet may be built up in the usual way. When inanition has been due to some disease not necessarily fatal, the same method of feeding may be relied upon to restore to health; but, of course, in cancerous and other destructive cases the treatment of the element of inanition is greatly circumscribed. Rectal alimentation should, however, always be maintained as long as possible.

A word should be added as to the use of fasting as a therapeutic measure, which formerly had more adherents than now, and was dignified with the name *cura famis*. With the increasing belief in the importance of maintaining nutrition for the sake of all vital processes, its application has become more and more limited. Its chief value is in the treatment of acute disorders of digestion, where the temporary withdrawal of food gives the organs a chance to obtain physiological rest.

Starvation, in whole or in part as to some articles of diet, has been made use of, from a therapeutic point of view, in the treatment of certain diseased conditions, notably obesity and diabetes.

Many years ago, one Banting, who was successfully treated by Harvey for obesity, wrote an account of the treatment pursued, from which the noun Bantingism and the grotesque verb "to bant" acquired a place in our language. The rules of Chambers, Banting, Cantani, and others amounted practically to a starvation cure, almost nothing but proteid food being allowed. They are open to the following objections: (1) They are usually tolerated for only a brief period, during which the patient is undergoing the "cure," and are not capable of being followed as a permanent rule and habit of life. Hence, after losing a few pounds of weight under their application, the patient returns with increased avidity to his original diet and at once regains what he has lost. (2) When persisted in, the starvation process is likely to aggravate an anæmia to which many obese persons are already liable, and hence to start a new chain of morbid processes. (3) An excessive albuminoid diet often leads to a loathing of all food, to indigestion, and chronic diarrhœa. (4) An exclusive albuminoid diet will, in supplying the necessary amount of carbon, cause the ingestion of something like four times as much nitrogen as the body requires, which overtaxes the eliminative system. (5) In reducing the fatty tissues of the body any starvation cure also reduces the albuminous elements, and so produces a failure in the nitrogenous equilibrium of the body.

The various mineral springs which have been recommended for the treatment of obesity, like Marienbad, Carlsbad, Kissingen, Soden, and Homburg, are effective only when conjoined with a dietetic regimen, and those waters which are strongly purgative are dangerous to many plethoric people.

The most satisfactory regimen for obesity is probably that of Ebstein, which is capable of maintenance permanently and does not incapacitate the patient for work. It contains, however, a qualitative and a quantitative diminution of food. The former, like that of Bantingism and the other starvation methods already noted, excludes carbohydrates. Sugar and sweets of all kinds are forbidden, as are also potatoes. Bread is allowed sparingly. The essential peculiarity of the method, however, consists in the addition of fats to the diet.

As the introduction of fat into the economy checks the decomposition of albuminoids, its effect as a constituent of the diet is to diminish the craving to make good that waste, or, in other words, to diminish hunger. Then the patient will require less meat in his diet. But whereas the amount of fat required by an average laborer is seven or eight ounces a day, Ebstein allows only about three ounces to his obese patient. He further limits the diet quantitatively, giving only three meals a day with three to three and one-half ounces of bread. The green and leguminous vegetables are allowed in small quantity. The proteid food, it is found, when accompanied by fat, can in itself be reduced from the thirteen to sixteen ounces allowed by Banting to two-thirds that amount.

An important addition to the dietetic treatment of obesity is the restriction of water and other fluids ingested. Although this point was made by some of the earlier writers, Oertel was the first to put it forward as a suggestion founded on scientific facts. The only alcoholic drinks allowed are a small quantity of a light red or white wine.

The dietetic treatment of diabetes is discussed elsewhere. But attention may here be called to the similarity in the restrictions called for in this disease and those called for in obesity. Also it will be noted that in both conditions the inclusion of fats in the diet facilitates the diminution in the harmful carbohydrate group. In applying even partial starvation methods for obesity, then, while we must limit the number of aliments allowed in order that the quantitative restriction may be more readily applied, we must beware of a too rapid and radical diminution in weight, and must make our regimen so tolerable that it can be continued as a permanency.

Charles F. Withington.

STASIS. See *Circulation, Pathology of.*

STATUS LYMPHATICUS.—(Synonyms: Constitutio lymphatica; Lymphatic constitution; Lymphatic habitus; Lymphatic dyscrasia; Lymphatic diathesis; Lymphatic chlorotic constitution; Lymphatism.)

Definition.—A so-called constitutional disorder characterized by a persistence or hyperplasia of the thymus and by general lymphadenoid hyperplasia, frequently associated with cardiac and arterial hypoplasia and the osseous evidences of rachitis.

History.—The term lymphatic diathesis is an old one in medical literature, and was no doubt applied to certain cases of status lymphaticus as above defined. Inasmuch, however, as scrofulous (see *Scrofula*) or tuberculous adenitis was particularly indicated by this ancient term, and that it was also applied to cases of pseudoleukæmia, chlorosis, and leukæmia, it is impossible to determine in how far it was definitely employed.

The most prominent anomaly of status lymphaticus, the persistent or enlarged thymus, was recognized by early pathological anatomists like Félix Plater (1614), Ch. Richa (1723), Bichat and Verdries (1726), and by Allan Burns, Franck, Kopp, Friedleben, and a number of others in the first half of the nineteenth century. (See also *Thymus, Diseases of.*) These pioneer students in their close attention to the thymus overlooked the accessory anatomical features of status lymphaticus; an error that has persisted to the present time and which has been productive of considerable confusion, since much of the literature bearing upon such clinical manifestations of status lymphaticus as laryngismus stridulus and sudden death is to be found by reference to the thymus alone. A clear conception of the lymphatic state was possessed by that pathological anatomist of wide and fruitful experience, Carl Rokitansky, who, in his text-book (1842–46), under the head of "Diseases of the Lymphatic Glands," mentions "lymphatic diathesis" or "lymphatic habitus." He observes that hypertrophy of the lymph glands occurs in childhood to puberty, or even beyond to mature life. The nodes of the abdomen (mesenteric and lumbar plexus) are most frequently involved, and this condition is commonly associated with hypertrophic development of other blood-forming organs, as, for instance, the thyroid gland, and more especially a highly developed spleen, "obstructed involution of the thymus," a hypertrophic state of the follicular apparatus of the intestines, and hypertrophy of the nervous centres. Such hypertrophies affect either the whole system or one portion, as, for instance, the glands of the abdomen. Under "Diseases of the Thymus Gland," Rokitansky says: "Its abnormal enlargement is almost entirely restricted to children, in whom we simultaneously observe a great predominance of the whole lymphatic system, rachitis, and hypertrophy of the brain." The hypoplasia of the heart and arteries, now acknowledged to be one of the frequently concomitant anomalies, commanded the attention of Wunderlich, Virchow, Rokitansky, Riegel, Kulenkampff, Bruberger, and Küssner between 1840 and 1880. On the assumption that vascular hypoplasia was fundamentally related to chlorosis, the condition was described by Virchow as the "lymphatic-chlorotic constitution."

Interest in the lymphatic state, both from the clinical and from the pathological standpoint, has recently been awakened, principally through the labors of the Vienna school, of which A. Paltauf, whose contribution in 1889 marked the new era, is a representative. The various morbid anatomical features of status lymphaticus were emphasized by Paltauf and illustrated by a series of careful autopsic studies. He revived the name "constitutio lymphatica," which is widely prevalent in recent German contributions; although, notwithstanding the care with which Paltauf endeavored to demonstrate the accessorial relationship of the enlarged thymus, one finds it still occupying the most prominent and often quite exclusive position in the reports of many recent writers.

Morbid Anatomy.—*Thymus.*—The predominant anatomical feature of status lymphaticus and the one that attracts attention most readily is the enlarged or persistent thymus gland. In children below the period of puberty the thymus of the lymphatic state is usually larger than in normal individuals. The enlargement of this organ has been repeatedly noted in infants dying by one of the several usually abrupt modes characteristic of lymphatism, and, as has already been said, this striking anomaly has often been noted to the exclusion of other accessory features. Such expressions as "thymus swollen," "thymus much enlarged," "thymus hypertrophic," appear in the autopsy protocols, together with data referring to the size and weight of the organ. The enlarged organ, which usually retains its bilobed shape, extends from the isthmus of the thyroid well down upon the pericardium, sometimes even to its diaphragmatic junction. Laterally, the thymus spreads after passing beneath the sternoclavicular union, generally expanding into two leaf-like lobes which reach a combined width of 5 to 6 cm. The thickness varies from 0.5 to 3 cm. The length of the enlarged thymus in children varies from 6 to 8 cm.; and its weight has been recorded as from 20 to 53 gm. Recklinghausen reports a thymus "as large as the liver of a new born infant" in a boy dying suddenly. A vigorous controversy has been waged as to the possibility of asphyxia from compression exerted by the swollen thymus upon the trachea at the point where the organ passes through the thoracic dome, the "critical space" of Grawitz, and some evidence seems to sustain the pressure theory as applicable to a few recorded cases.

It is generally conceded that the thymus in normal individuals undergoes an involution after the second or third year, and that this involution is usually complete at or soon after puberty (see *Thymus*). But in victims of status lymphaticus the involution of the thymus is retarded, in consequence of which a persistent and sometimes hypertrophic organ is encountered in adults, particularly those less than forty years of age. The location of this persistent thymus corresponds to that in children, and the state of enlargement varies in individuals as shown by the recorded weights of 20–135 gm.

Both in children and in adults the thymus of status lymphaticus resembles in appearance the normal organ of infancy. It is pinkish or flesh-like in color; and a distinct lobulation like that of the sweetbread of the calf, often with clearly outlined follicles, is seen. Its consistence is soft. Hemorrhages and consequent ecchymoses are present in certain cases, particularly those in which asphyxia has accompanied the sudden death. At times the thymus is the seat of an active hyperæmia, and a few instances are recorded in which a milky juice exuded from the cut organ.

The pathological histology of the thymus of status lymphaticus is not yet thoroughly elucidated, and more careful studies of a large material by the use of recent methods is highly desirable. In a general way it appears that the enlarged organ reproduces the microscopic structure of the normal thymus of infancy, differing only in the multiplication of the lymphoid cells which serve to increase the size of the follicles, and to produce new ones both in the normal sites and in the adipose tissue surrounding the gland proper. The normal division of the thymic follicle into cortex and medulla is usually retained, though the hyperplasia of lymphoid cells tends to invade the medulla and to infiltrate the trabecula of the follicles. Some authors have described an increase of eosinophilic leucocytes in the enlarged thymus, but we have evidence that this is not a constant feature. Endothelioid cell proliferation has also been described.

But while persistence and hypertrophy of the thymus is a prominent characteristic of status lymphaticus, it is not an invariable one, for we may have a non-thymic lymphatism in which general lymphadenoid hyperplasia and arterial hypoplasia exist with a thymus of normal size or one that has undergone perfect involution.

Further, it is well to recall that the anatomical evidences of the lymphatic state may be erased by a number of different causes, and that the thymus is one of the earliest structures so affected. Advanced years, particularly after the fortieth, usually induce rapid subsidence of the enlarged lymphatic structure. Various chronic diseases, and particularly those associated with debility, marasmus, and wasting, act similarly. Some acute diseases may produce the same effect.

Lymphadenoid Hyperplasia.—A generally hypertrophic state of the lymphadenoid tissue is, next after the anomaly of the thymus, the most noticeable evidence of status lymphaticus. This is shown by an increase in the size and number of the lymph follicles in various portions of the body. In the lymph glands, both superficial and deep, it is made apparent by their increased size and also, at times, by enlargement of the individual follicles. Sometimes the superficial lymph glands are not particularly augmented, while those of the abdomen, especially of the mesentery, are affected. Usually the enlarged lymph nodes remain discrete, but there may be a diffuse increase of lymphatic tissue, particularly in the mesentery.

In the respiratory and gastro-intestinal tracts the lymph follicles are generally very prominent. The faucial, lingual, and pharyngeal tonsils, with the intervening solitary follicles, and those at the base of the tongue, in the larynx, œsophagus, and stomach, participate in the process. In the intestines both the solitary follicles and those aggregated in Peyer's patches are unduly prominent. A distinct adenoid ring may appear occasionally in the duodenum, and more frequently at the ileo-cæcal junction. In the small intestine, and particularly in the lowermost portion of the ileum, the follicles of Peyer's patches may protrude above the surface of the mucosa, sometimes appearing as subspherical projections half a centimetre in height; and such augmented patches may reach a length of 9–11 cm. Here the solitary follicles also project prominently, at times even taking the appearance of polypoid outgrowths. In the colon an increased prominence of the solitary follicles, with their pit-like central areas still remaining, is observed. Taken as a whole, the hyperplasia of the lymphatic structures of the intestines in status lymphaticus closely simulates that seen in the stage of swelling of typhoid fever, and might readily be so mistaken.

The retroperitoneal lymph glands usually participate in the hypertrophy, to the same degree as that observed in the mesenteric nodes; and the bronchial glands are also involved, although not invariably. Of the superficial nodes, those of the inguinal, popliteal, axillary, cervical, supra- and infraclavicular regions may be affected to a varying degree, but usually not extensively. Collections of lymphoid cells have been described in the liver, thyroid, and bone marrow, and Kundrat cites a case in which red marrow was present in the shaft of the femur.

Spleen.—A moderate enlargement of the spleen is the rule in status lymphaticus, while the prominence of its Malpighian bodies is more striking. Generally, the splenic pulp is firm, the organ filling its capsule well. In cases of sudden death in individuals of robust condition the splenic pulp is hyperæmic. In the midst of the more or less deeply colored pulp the follicles composing the Malpighian bodies stand out with startling distinctness as pale round areas, often measuring 2–3 mm. across, and resembling large miliary tubercles.

Histologically one finds the enlarged Malpighian bodies to consist of closely packed small lymphoid cells, generally surrounding the arterioles and supplied with few blood-vessels, thus contrasting sharply with the adjacent pulp tissue with its dilated and engorged blood sinuses. Not infrequently the hyperplastic lymphoid cells of a follicle will infiltrate diffusely into the adjoining pulp tissue, and at times small foci of lymphoid elements, without direct connection with a well-formed follicle, will be found scattered throughout the splenic substance.

The dilated sinuses of the splenic pulp are filled with blood, and in some cases evidence of extensive hæmolysis and the deposit of blood pigment appear in the pulp cells.

Cardiac and Arterial Hypoplasia.—In certain cases of status lymphaticus, particularly those coming under Virchow's class of "lymphatic-chlorotic constitution," a pronounced hypoplasia of the arteries, and sometimes of the heart as well, has been noted. Some authors have described a general arterial narrowing, others a narrowing of the aorta; in fact, so far as the aorta is concerned, a diminution in calibre has been pretty uniformly discovered. In view of our ignorance as to the causation of aortic narrowing, whether real or only apparent and due to varying degrees of elasticity, we are not prepared to assert just what is the nature of the change found in victims of status lymphaticus; but that the aorta, at times the general system of arteries, and rarely the heart, are smaller than the same structures in average normal individuals is unquestionable. Even in adult lymphatic males of full stature and well developed otherwise, an aorta measuring but 4 cm. in circumference at its cardiac end has been found, and a circumference of 5 cm. at the aortic ring is the rule. These narrow aortas are usually thin-walled and quite elastic. Rupture of such thin-walled arteries has been reported; and in certain cases in which the heart also was hypoplastic, a patent foramen ovale has been found.

Rachitic Bone Changes.—That there is a close morbid anatomic association of status lymphaticus and rickets is abundantly proven, particularly in the case of lymphatic infants. Still we are not at present in a position to say that all cases of status lymphaticus are associated anatomically with the rachitic dyscrasia, nor do all cases of rickets exhibit the evidences of lymphatism, though its coincidence with enlarged spleen and hyperplasia of the mesenteric nodes is well known. In infants dying in the lymphatic state a mild grade of craniotabes, the rosary, curvature of the long bones or spine, and enlarged epiphyses, have been manifested as rachitic osseous changes; and in older children or adults several instances of rachitic spinal curvature, pigeon breast, narrow pelvis, and curvature of long bones have been found. Microscopically the affected bones present the lesions characteristic of rickets.

Skin.—A thick skin and an increased fat layer have frequently been noted among the anatomical findings. In the skin an increase of the elastic elements has been described as a factor in augmenting its thickness. Pallor of the skin of the peculiar kind known as pasty ("pasteos") is looked upon as an evidence of lymphatism.

Blood.—Observations upon the blood in status lymphaticus are still meagre, and a unanimous opinion as to the characteristic alterations has not been reached. One would expect a lymphocytosis in these cases, and this has been reported in several cases. Thus Ewing found a pronounced increase in the number of mononuclear large and small lymphoid cells in the blood of one of his cases, and he suggests that further systematic search may reveal this as a constant condition. In the red cells no abnormality in number or structure has been detected.

Occasional Features.—In many of the cases of sudden death among the victims of the lymphatic state a pronounced active hyperæmia of the thoracic and abdominal viscera, and occasionally of the brain, has been described. Further, particularly in those sudden deaths in which asphyxia figured, hemorrhagic ecchymoses of the pericardium, thymus, pleura, and endocardium were present in the order of frequency of the structures mentioned.

Hypertrophy of the thyroid is a quite common accompanying anomaly. There may be a simple hypertrophy, a parenchymatous goitre, or a cystic goitre. In about one-half of the reported cases the thyroid has been found enlarged.

Œdema of the skin, or more commonly eczema, is occasionally found. Œdema of the lungs has been discovered in some cases of sudden death in lymphatic individuals; and in lymphatic epileptics dying after one or several attacks, or from rapid status epilepticus, this condition is encountered as the general rule.

Hypertrophy of the brain is mentioned by Rokitansky as one of the features of status lymphaticus, at times combined with cerebral œdema or with widening of the ventricles and increase of intracerebral fluid. In some of the recently studied cases one or more of these conditions are mentioned, and, in certain epileptics in the lymphatic state, general cerebral hypertrophy, localized hypertrophy, œdema, or hydrocephalus may appear.

On the side of the sexual organs peculiarities are occasionally encountered. A retarded development of the external genitals and the delayed appearance of the beard, the pubic and axillary hair in the male, are examples of these. In the female an infantile (and sometimes double-horned) uterus with undeveloped tubes, ovaries, and mammæ, together with a masculine aspect of the whole body, are likewise occasionally found.

Before dismissing the subject of the morbid anatomy of status lymphaticus we should emphasize the fact that a number of the characteristic features are profoundly modified by the individual's state of nutrition. In those victims of status lymphaticus who die suddenly in a good state of nutrition such anomalies as the large thymus, lymphadenoid hyperplasias, and thick fat layer appear prominently; but when nutrition has suffered through the exhausting influence of chronic diseases or the rapid wasting of certain acute affections, these structures atrophy along with the rest of the body. On the other hand, the aortic or arterial hypoplasia, and the osseous changes of ancient rickets are ineradicable, though these, it must be remembered, are not invariably present.

Again, one may find status lymphaticus associated with certain other diseases and their anatomic changes, as, for example, Basedow's disease, struma, scrofula, and pseudoleukæmia.

Clinical Manifestations.—Status lymphaticus has been found in a number of diseases in which the association seems to have been more than a mere coincidence.

Thymic Asthma.—Up to very recent times that peculiar spasmodic neurosis known as spasm of the glottis, laryngismus stridulus, child-crowing, or by the term "asthma thymicum" given by Kopp in 1824, has been looked upon as having its morbid anatomical basis in an hypertrophy of the thymus. But in the last decade more exhaustive studies have disclosed one or several of the other features of the lymphatic state in these cases, and there need now be little hesitancy in considering this affection as one of the clinical evidences of the latter condition and in describing it in this connection.

Thymic asthma, a disease of infancy, may be defined as a paroxysmal suffocation, and is a not uncommon cause of sudden death, especially between the fourth and tenth months. Its symptomatology has been well described by Kopp, and more recently by Pott. In a typical fatal attack the child suddenly jerks its head backward with a sharp noisy inspiration like that of whooping cough, but sharper and shallower; the eyes are upturned, fixed, and pupils dilated; the face has a painful, anxious expression, is blue at first and then pallid; the nostrils are dilated. The tongue swells and arches so as to press against the hard palate, while the veins of the neck become engorged and stand out prominently. The arms assume a condition of tonic extension with fists clinched and thumbs turned into the palms. The legs become extended, great toes abducted and dorsally flexed. An attitude of opisthotonos is assumed by the spine. A convulsive tremor of the facial muscles and an ineffectual gasping inspiratory attempt follow. Suddenly the spasm ceases, the face becomes ashy, then cyanotic; the tongue and lips are livid; and after one or two minutes the child is a corpse. Urine and fæces are involuntarily passed if artificial respiration is attempted. The heart ceases its activity at the onset of the paroxysm; its sounds are inaudible and the pulse is absent. Reflex irritability is lost. In attacks not fatal the clinical phenomena resemble those just described; there is the abrupt onset, the paroxysm of suffocation and convulsive movements of various groups of muscles, often with involuntary evacuations, and occasionally with complete loss of consciousness. Friedleben, one of the older observers, states that these attacks occur most frequently in well-nourished infants, though they may appear in the debilitated. The interval between the spasms may be hours, days, or weeks, though they tend to increase in frequency and severity. Twenty to forty attacks have been noted in twenty-four hours. The period of the first dentition is the one particularly prone to this affection, though it has been recorded in the new-born infant. The so-called idiopathic spasm of the glottis of adults is probably dissimilar at least in so far as its relations to status lymphaticus are concerned, though this point has not been definitely settled.

Thymic asthma and thymic sudden death in infants stand so closely allied as to make a separate consideration unnecessary, for while many infants have succumbed suddenly, in which, for want of actual observation or for lack of trained observation, none of the symptoms of thymic asthma has been described, it is highly probable that one or more of the convulsive phenomena just mentioned actually preceded death. Many of these sudden deaths in infants are tragic occurrences, and not infrequently they have called for medico-legal investigation. Some of the children in seeming good health have expired abruptly in the presence of spectators or even in their parents' arms (Grawitz and others); they have been found dead in bed, and suspicions of foul play have been entertained against a mother or nurse under these circumstances; or death has been ascribed to suffocation in the bedclothes. Some, at least, of the deaths from fright recorded among children doubtless belong to this same category, and here also probably belong those occasional instances in which animals like cats or dogs have been suspected of causing the death of infants, as in those popularly described as "cats sucking the breath."

As to the etiology of thymic asthma and thymic sudden death the controversy aroused by Kopp's theory is still waging. Kopp maintained that the weight of the enlarged thymus on the heart, lungs, and great vessels induced the spasm of the glottis either by direct pressure or by irritation of the recurrent laryngeal nerve. Even to the present time the mechanical theory advanced by Kopp is accepted by some authors, or the modification of it proposed by Grawitz, who held that direct compression of the trachea is produced by the swollen thymus at the point where it emerges from the dome of the thorax ("critical space"), particularly when the head is suddenly drawn backward. Ever since the time of Friedleben's masterly studies upon the diseases of the thymus (1858) the pressure theory has been combated, and a large controversial literature has appeared. That the mechanical factors are concerned in some of these cases seems undeniable, but even in those in which the marks of tracheal compression are indubitable, it is still impossible to say that compression alone was the active agency in exciting the spasm or the sudden death. Because of the inadequacy of the mechanical theory to explain the majority of the cases, the tendency in the last few years has been more and more toward the view advanced by Pott, and extended by Paltauf. Pott believed the fatal issue to be ascribable to sudden arrest of the heart, though he charged the cardiac affection to the results of pressure of the suddenly congested and already hypertrophied thymus upon the trachea, pulmonary artery, and right auricle. Paltauf also ascribes thymic sudden death to a spasmodic arrest of the heart, but he goes beyond the thymus and looks to status lymphaticus as the responsible condition. He points out that the enlarged thymus coexists with general lymphadenoid hyperplasia, and arterial hypoplasia—that is, with the lymphatic state—and that the victims of this dyscrasia possess a lowered vital resistance and a particular proneness to convulsive disorders, among which cardiac or respiratory spasm or paralysis are the most dangerous. In this light, spasm of the glottis or thymic asthma becomes a reflex respiratory spasm, and thymic sudden death a reflex cardiac paralysis, both in some way dependent upon the exaggerated irritability incidental to status lymphaticus.

Infantile Eclampsia.—That teething fits are often associated with rickets has been pointed out by a number of authorities. The relationship of infantile eclampsia and status lymphaticus has not been emphasized, but there is reason for believing that this convulsive neurosis, like glottic spasm, occurs in lymphatic children. In a few cases eclampsia and spasm of the glottis have been noted in the same infant in which status lymphaticus was disclosed at autopsy. As we shall see in the section following, tetany is one of the neuroses frequently combined with eclampsia and one in which status lymphaticus has been found to exist. It therefore appears quite proper, even in the absence of an abundance of direct evidence, to discuss the general convulsions of infancy in their present connection; and the writer is of the belief that more careful study from the point of view just indicated will show the correctness of this position. I have, during the last year, had the opportunity of performing an autopsy on a six months' infant dying of general convulsions, and found a large thymus with pronounced hyperplasia of the intestinal and splenic follicles, and hypertrophy of the mesenteric glands.

Idiopathic Tetany of Infancy.—Closely allied to spasm of the glottis and eclampsia is the carpopedal spasm of infancy which is, by most recent authors, classed as infantile idiopathic tetany. Tetany in infancy may manifest itself by carpopedal contractures alone, which occur in intermittent attacks or very rarely as a persistent spasm; it may exist as a latent affection, only showing under certain conditions of irritation; it occurs in combination with laryngeal spasm, or with laryngeal spasm and eclampsia. Its relations to rachitis have been repeatedly pointed out, and discussions as to the invariable association of craniotabes and tetany and the causative influence of the former have frequently arisen. The association of tetany and status lymphaticus has been emphasized particularly by Eschereich, whose opportunities for the study of this and its allied neuroses have been especially good. He affirms that the lymphatic state may exist as a complication of tetany, and that it is of especially grave import. The various anomalies of status lymphaticus have been disclosed in autopsies on victims of tetany, although not always recognized in their proper connection.

Epilepsy.—A mention of persistent thymus in epilepsy was made in 1890 by Kruse and Cahen, based on their finding this anomaly in autopsies on two epileptics. The association of epilepsy with status lymphaticus has been particularly emphasized by the writer as the result of his studies in the Pathological Laboratory of the Ohio Hospital for Epileptics. In autopsies upon the victims of idiopathic grand mal, particularly in young and robust individuals, evidence of the lymphatic state occurs with a regularity that suggests more than an accidental relationship, though the tracing of a possible causal connection between epilepsy and status lymphaticus is at the present time largely a matter of speculation. I have already noted that a clinical kinship has been traced between epilepsy and the neuroses above mentioned, particularly infantile eclampsia and spasm of the glottis, and, as already suggested, these neuroses have been associated both with rickets and with the lymphatic state. As for epilepsy, no less an authority than Gowers has concluded from purely clinical and statistical observation that rachitis must be looked to as a fundamental factor in the occurrence of teething fits and more remotely of the epilepsy which so frequently follows in a victim of infantile eclampsia. My studies in the morbid anatomy of epilepsy have revealed the evidence of an ancient rickets in a proportion of cases, and the anomalies of status lymphaticus as a relatively constant occurrence in the subjects of idiopathic grand mal dying under circumstances favorable to the retention of the anomalies of the lymphatic state.

Epileptics are very prone to sudden and often tragic deaths, as by asphyxia (sometimes mechanical, sometimes not), "syncope," "heart failure" without anatomical cardiac lesions, rapid status epilepticus, œdema of the lungs, "cramps," and drowning, and I have endeavored to define an affinity between the sudden death in epilepsy and that seen in such neuroses as thymic asthma, the various forms of thymic sudden death of infancy, and those in adults presently to be described.

Death in Surgical Narcosis.—Gradually, but more particularly since the report upon Kundrat's observations, we are coming to learn that status lymphaticus is to be held responsible for most of the deaths in chloroform anæsthesia, and probably for many of those occurring in surgical narcosis by the use of other agents like ether, nitrous oxide, etc. Our information concerning chloroform sudden death is particularly definite because of the almost exclusive use of this drug in Austria and Germany, where, to the present time, thorough autopsies with the possibility of discovering the existence of status lymphaticus have alone been practised. Unquestionably when we come to make a careful anatomical analysis from the standpoint just indicated we shall find the conditions attending anæsthetic accidents in America identical with those recorded in Europe; though the impression now seems to prevail that chloroform *per se* is the especially dangerous anæsthetic in victims of the lymphatic state.

As to the time and mode of death no regularity has been determined. Any stage of anæsthesia from the first few whiffs to the completion, or during the period of recovery, or even several hours after the narcosis and operation have been ended, may be selected as the fatal moment. Death may be very abrupt with evidence of cardiac and respiratory failure, or the patient sinks more gradually with enfeebled pulse and shallow respiration. Methods of resuscitation, such as avail in the ordinary accidents of anæsthesia, are here fruitless.

For their protection in cases of the often distressing accidents of surgical narcosis it is important that the surgeon and anæsthetizer keep clearly in mind this now well-established association of status lymphaticus. Unfortunately, our means of ante-mortem diagnosis in status lymphaticus are at present quite unsatisfactory, particularly in the case of adults. In children the existence of adenoids, enlarged tonsils, enlarged superficial lymph nodes, and osseous rickety changes, together with a history showing eclampsia, laryngismus stridulus, or idiopathic tetany, should be seriously considered as having grave prognostic importance.

Death from Trivial Surgical and Medical Procedures.—Closely allied with the sudden death in surgical narcosis are those which occasionally follow minor operations. In some of these, especially those in which incomplete anæsthesia has been employed, it is questionable in how far the anæsthetic or the shock of the operation is to be held accountable for the fatal termination. Illustrations of this point are the deaths which have followed operations for the removal of nasopharyngeal adenoids. Here a partial anæsthesia is commonly employed, and most of the sudden deaths have been found under these conditions.

Although the point has not yet been prominently emphasized, I am personally inclined to the belief that careful study will reveal all the unexpected deaths following adenoid operations (including those on hypertrophied tonsils), either with or without anæsthesia, to be associated with status lymphaticus. It is at least pertinent to recall that the lymphatic overgrowth making the basis of nasopharyngeal adenoids and enlarged tonsils is one of the manifestations of status lymphaticus.

Allied to the accidents just alluded to are the deaths occurring in other minor operations done in incomplete anæsthesia, and heretofore ascribed either to the anæsthetic alone or to the shock and drug effect combined. A well-known illustration is the occasional fatal accident during or after the extraction of a tooth. The occasional deaths after minor accidents, and following various trivial operations in which no anæsthetic is used, will doubtless gradually find their way into the group of neuroses associated with the lymphatic state.

A particularly appropriate illustration concerns the sudden deaths following the injection of curative sera, of which the first pronounced example was in the case of the young son of Professor Langerhans, of Berlin, who died suddenly a short time after the injection of a small dose of diphtheria antitoxin, used by his father for preventive purposes. At the time of the occurrence this case excited much discussion, and various theories were put forward to explain the accident, especial stress being laid upon the possible toxic effect of the antitoxin. However, the autopsy revealed certain evidences of status lymphaticus like swollen spleen with prominent follicles, enlarged tonsils and pharyngeal follicles, hyperplastic intestinal follicles, and slight rickety thickening of the costosternal margin; and while these were not taken into serious consideration during the immediate examination, they were dwelt upon later, and by such experienced students as Paltauf, Escherich, and others, it was concluded that this unfortunate accident was one of the fatalities of the lymphatic state.

Escherich reports the case of a lymphatic child who died in a salicylic-acid pack. Galatti records a similar fatality after an external application for eczema; the child developed tonic and clonic convulsions, and died in twenty-four hours, and here Kolisko found, along with the eczema, œdema of the brain, rachitis, and anæmia with evidence of lymphatism. In connection with his case Escherich points out the danger of narcosis, prolonged hydrotherapeutic treatment, or weakening therapeutic measures in children with status lymphaticus.

Sudden Death in Adults, and Death in the Water.—Abundant evidence has accumulated to show that adults, especially young, apparently strong individuals, are, like infants and children, the subjects of status lymphaticus and therefore exposed to such accidents as sudden death under the various circumstances just related, as that in surgical narcosis and after trivial operations. Death in the water by so-called "drowning" is one of the modes noted more particularly in adults, though mentioned in the case of some infants. In some of these fatal accidents the victims have been found dead with no external evidence to indicate the mode of termination. Others have died before spectators by a variety of tragic methods. A number have expired in the water with so-called "cramps" or by "drowning," in which the usual post-mortem findings of fatal immersion were absent. Most of these occurrences have demanded medico-legal investigations, and their importance from this standpoint is so great that it seems desirable to illustrate the subject by citing some typical cases.

Nordmann describes the case of a twenty-six-year-old scavenger, in apparent good health, who was found dead in the situation of his work. Autopsy showed the body of a medium sized, strongly developed man, with diffusely ecchymotic skin; tonsils and papillæ of the tongue prominent; lungs congested and moist; heart ecchymotic; flesh somewhat thickened, tough, and pale; liver and kidneys dark and hard; thymus persistent and enlarged, measuring 7 × 5 × 1.5 cm.; lymph glands in neck, axilla, and mesentery much enlarged and pale; aorta narrow (5.5 cm. above valve), wall thin and smooth.

Another case, noted by Nordmann, is that of a twenty-five year old man who died suddenly without assignable cause while playing cards with several companions. Section (by Kaufmann) revealed a thymus gland, thin, but as large as the palm of the hand, general hyperæmia; flaccid, slightly dilated heart, and slight enlargement of lymphatic glands and follicles.

Still another case recorded by Nordmann illustrates a form of sudden death after bathing. A soldier in good physical condition, twenty-six years old, went bathing on a warm August afternoon with a number of comrades. All precautions were taken as to the proper temperature of the water. He entered the water slowly, swam about for two or three minutes, and returned to the shore. After emerging from the water he complained of chilliness, suddenly stiffened his extremities, became pale, turned his eyes upward, and with a long-drawn inspiration fell to the ground. He was assisted to a sitting posture, where Nordmann found him pulseless, with a deeply cyanosed face, and after two or three spontaneous attempts at breathing respiration ceased. Artificial respiration and stimulation were of no avail. On autopsy the body was found to be well formed, in good nutrition, with pronounced rigor, and cyanosis of the face. The brain was merely congested. The thoracic organs were entirely normal. Bronchial glands were somewhat enlarged, gray-black, and a little firmer than usual. A thymus gland, larger than a fist, lay in the anterior mediastinum, dark red in color, with follicles plainly visible. The tonsils were enlarged, as were also the lymph glands, and the follicles of the tongue and spleen. The thyroid was symmetrically enlarged.

Several instances have been reported in which people in apparently good health suddenly fell into the water, and, although at once removed, before death by asphyxia could possibly have occurred, could not be resuscitated. A thirteen-year-old boy fell unexpectedly from on board a ship in the docks, and although immediately removed from the water, could not be revived. The autopsy was conducted by von Recklinghausen, who reports, aside from an enlarged thymus, enlarged tonsils and lymph glands, nothing abnormal. Another case noted by von Recklinghausen is that of a man, twenty-seven years old, who, while bathing in a forbidden spot, was suddenly accosted. He arose from the water frightened, and at once fell, to sink below the surface. He was promptly dragged from the water, but did not revive. Section of the body of this large, lean, well-formed man showed a general hyperæmia; flaccid, dilated heart, with a tough myocardium and normal valves; and slight narrowing of the ascending aorta. The lymph glands in the neck, axilla, mesentery, and the tonsils were enlarged and pale; the follicles of the spleen, tongue, and epiglottis were swollen (intestinal follicles not mentioned). In the anterior mediastinum a persistent thymus measuring 9 × 6 × 1.5 cm. was discovered.

At least two well-authenticated examples of thymic and lymphatic hyperplasia in individuals sinking suddenly while swimming are described by Nordmann in his excellent paper upon the relation of the thymus gland to sudden death in the water. These two cases Nordmann credits to von Recklinghausen. A twenty-year-old mechanic, while swimming, uttered a sharp cry and sank beneath the surface, and, though promptly removed from the water, was dead. On post-mortem examination his body was found to be lean; the organs were generally congested; the lymphatic glands in the neck, axilla, and groin were enlarged, along with the spleen. The follicles in the nose, glottis, and tongue were very prominent. The thymus was persistent and measured 10 × 6 × 1 cm. In the other case a man twenty eight years of age suddenly sank while swimming beside some companions. He was at once removed from the water, but death had already taken place. The body was well nourished. The noticeable features of the section were the enlarged tonsils, lymph glands, and spleen; and the hyperplastic follicles of the tongue, spleen, and intestines (Peyer's patches). The heart was flaccid, and the aorta measured but 4 cm. at its origin. The thyroid was enlarged. The persistent thymus was 10 × 8 × 1 cm. in size.

Lower Resistance to Infection.—A predominant peculiarity of the constitutional condition which we are considering is, as Paltauf and others have shown, a lowered vital resistance, and this is apparent in the event of certain acute infections. Diphtheria, as demonstrated in Escherich's clinic by Moriz Daut, tends to assume a particularly severe type and to prove frequently fatal in lymphatic infants and children. Between the years 1890 and 1897 there were seventy-nine deaths from diphtheria in the clinic at Graz, and twenty-three of these showed status lymphaticus. Susceptibility to diphtheria in lymphatic children shows itself in several ways. Thus in the midst of an otherwise mild epidemic the lymphatic victims may die early in the attack with no diphtheritic anatomical lesions to explain the unexpected ending. There are hoarseness of the voice, hoarse cough, and a tendency to suffocation. Only a thin false membrane is present in the throat and larynx, and nowhere is there a mechanical obstacle to explain the hoarseness and dyspnœic symptoms. One or two days after entering the hospital the children become much worse; after coughing, severe dyspnœa and cyanosis appear with a small, weak, irregular pulse; consciousness is lost, and death supervenes in spite of various heroic efforts at resuscitation, including intubation or tracheotomy. In another class of cases there is a pronounced tendency to rapid extension of the diphtheritic exudate into the bronchi and bronchioles with bronchopneumonia following. Here, of course, the anatomical findings fully explain the fatal termination. This also holds true for the septic type of cases with early death; but the point is made that subjects of status lymphaticus are, from their constitutional weakness, especially prone to suffer severely from this infection. All the ordinary therapeutic efforts for diphtheria fail in these cases, and such is likewise the case with the extraordinary measures like tracheotomy and intubation. It is here also that the specific serum, the antitoxin of diphtheria, fails to exert its usually prompt and beneficial results. Even in early cases in which antitoxin usually produces a marvellous effect, none follows, and this seems to be independent of the dosage, for Daut, in his cases, used the antitoxin promptly and freely. It is very desirable for physicians generally to be clearly informed as to the unfavorable prognosis of diphtheria in status lymphaticus, and especially as to the possibility of failure with that sovereign remedy—antitoxin—in this class of individuals. Alike is the danger of accidents following the use of a prophylactic antitoxin injection, and, in the absence of the specific therapeutic response to the remedy, it behooves the practitioner to be on his guard both for his own protection and to spare ill repute to so valuable a therapeutic agent as the antitoxin of diphtheria. We have had, at the Ohio Hospital for Epileptics, three cases of fatal diphtheria in adult epileptics in which we ascribed the unexpected termination to the existence of a status lymphaticus as demonstrated at autopsy. In each of these cases antitoxin treatment was unavailing.

Among other infectious diseases toward which the resistance of lymphatic subjects is lowered may be mentioned cholera as shown by Virchow, pneumonia by Ortner, typhoid fever by Fraentzel, Virchow, and Hiller. Ortner found pronounced evidence of status lymphaticus in some fatal cases of anæmia after removal of the exciting cause, Bothriocephalus latus, and he holds the connection to be more than a coincidence. In most of the cases just mentioned the especially prominent anomaly was the hypoplasia of the heart and arteries, the cases being, in fact, examples of Virchow's "lymphatic chlorotic constitution."

Bronchial Cough.—West has reported several cases in which a harsh, spasmodic, croupy cough was assigned to the irritation of enlarged bronchial lymph nodes and which improved under the administration of creosote. The enlarged and offending glands were looked upon as manifestations of lymphatism, of which the patients exhibited certain other clinical manifestations like enlarged superficial lymph glands, hypertrophied tonsils, palpable spleen, dulness over the upper sternum, and, in half of the cases, evidences of a previous rachitis.

Association with Other Diseases.—As has already been stated, hypertrophy of the thyroid, *i.e.*, goitre, has been found in about one-half of the cases of status lymphaticus in adults. This may be simple goitre or it may take the form of exophthalmic goitre. Möbius, in 1891, emphasized the concurrence of persistent thymus and Basedow's disease, and this has been verified by Mosler, Spencer, Johnston, White, Ross, Bradford, Hektoen, and a number of others. Several of these cases died abruptly under circumstances strongly suggestive of thymic sudden death as now recognized, and in the several thorough autopsies, besides the persistent and hyperplastic thymus, such lymphatic alterations as prominent intestinal and splenic follicles, etc., have been described. In explanation of this syndrome it is urged that experimental evidence points to some sympathetic relation between the thyroid and thymus as shown by the enlargement of one following the extirpation of the other. It is also suggested that the tachycardia of exophthalmic goitre is analogous with the tendency to cardial paralysis in status lymphaticus.

As long since shown by Virchow, hypoplasia of the heart and arteries is frequently associated with chlorosis, and Copeland and Bamberger noted the coincidence of hæmophilia with aortic narrowing. It has also been found that other features of the lymphatic state are associated with the hypoplasia of the heart and arteries, and this, recognized by Virchow, led him to define the condition as the "lymphatic-chlorotic" constitution.

The extensive hyperplasia of lymphadenoid tissue in status lymphaticus brings it anatomically to resemble some cases of leukæmia and pseudoleukæmia. In the latter conditions we not only encounter enlargement of the lymph glands and lymph follicles, but hypertrophy or lymphoid overgrowth of the thymus as well. There seems, however, to be little or no clinical analogy between these affections. The blood changes, like the anæmia, and the disturbance of balance in the various kinds of leucocytes are either entirely absent in status lymphaticus or but imperfectly exhibited by occasional lymphocytosis. Ewing has shown that while the enlargement of the intestinal follicles may reach the extent observed in less pronounced pseudoleukæmia, in the latter disease the small nodules of lymphoid tissue grow laterally for some distance before producing much elevation of the mucosa, contrasting with the sharply circumscribed, abruptly projecting follicles of status lymphaticus. The nodules of pseudoleukæmia frequently ulcerate at their central points owing to improper blood supply, here again differing from the well-vascularized follicles of lymphatism. Ewing remarks: "In the majority of the cases of lymphatic constitution the enlargement of the lymph nodes does not pass beyond the limits of what may be called a physiological hypertrophy, and bears little resemblance to a tumor formation. The spleen is rarely much enlarged. The presence of considerable pigment in the spleen pulp is too ordinarily seen to be interpreted positively as the result of an excessive blood destruction, such as characterizes the severe anæmias. Yet it must be admitted that the very considerable degree of pigment deposit reached by the two cases referred to above* indicates that in some instances the blood has suffered severely. These children are, however, not usually anæmic, but in excellent health, and even the sickliest of them do not resemble cases of infantile leukæmia, pseudoleukæmia (von Jaksch), or chlorosis. As for the hyperplasia of the lymphoid marrow, it may be said that the normal limits of lymphoid marrow are as yet by no means definitely settled. Such hyperplasia may be seen also in the secondary anæmias, and in any case the hyperplasia of the lymphoid marrow may be regarded as merely a part of the general and more or less physiological hypertrophy of the lymphoid structures of the body."

Diagnosis.—Paltauf distinguishes two varieties of status lymphaticus, one rachitic, the other non-rachitic. In the first group a pale skin, well-developed fat layer, enlarged spleen and thymus, with lymph glands and follicles in varying grades of enlargement, and the epiphyseal changes of rickets are prominent; while in the second the pale skin, rich fat layer, and pronounced hyperplasia

* Cases reported by Ewing.

of the lymph glands and follicles, with a thymus above the average, are encountered

As a rule, the subjects of status lymphaticus appear in what we are pleased to call a well nourished condition, though its anomalies are sometimes found in debilitated subjects, particularly in infants advanced in rickets. The lymphatic infants usually appear plump and well-fed; the adults are robust, even inclining to moderate corpulence, and the young adult males are generally well-built, well nourished, and even decidedly athletic in appearance. In infants, however, notwithstanding the appearance of good nutrition, a condition of perfect health is contradicted by the peculiar pallor of the skin and the flabby state of body. The skin is both pale and of the condition called pasty, giving, as the Germans describe it, the "pasty habitus." A tendency to eczema, either of the head or universal, is quite common in lymphatic infants. In adults the thick, coarse skin, and muddy complexion are found

For purposes of diagnosis, aside from the general features just noted, it becomes important to discover, if possible, the evidences of a general or local hyperplasia of lymphatic structures and of narrowing of the arteries where this is associated. The hypertrophy of the faucial, lingual, or pharyngeal tonsils, of the "pharyngeal ring," with augmented prominence of the follicles at the base of the tongue, should, if accompanied by enlargement of the cervical, axillary, or inguinal glands, suffice to arouse suspicion, as Ewing says. The mesenteric glands may occasionally increase until they become distinctly palpable tumor-like masses. Generally the spleen is enlarged to a point which can be determined by careful exploration. Hypertrophy of the thymus manifests itself by increased substernal dulness, and has, especially in infants, been detected during life and confirmed at autopsy. In adults, and especially in the well-nourished, enlargement of the thymus of the relatively moderate grade incidental to status lymphaticus is not easily demonstrable by physical examination. It may be possible under exceptionally favorable conditions to detect hypoplasia of the peripheral arteries both by their reduced size and by their increased tension, and Ortner noted an absence of aortic pulsation in the neck in his cases which he regards as pathognomonic if found in a muscular subject. Hypertrophy of the left ventricle, and dilatation of this chamber have been mentioned as accompanying aortic hypoplasia.

The frequent association of rachitis with status lymphaticus should always be in mind, and when one or more of the osseous manifestations of rickets appear, along with lymphatic enlargement, increased thymic dulness, etc., a diagnosis of the lymphatic state may safely be hazarded. In infants a mild grade of craniotabes, retarded closure of the fontanels, retarded dentition, the rosary, enlarged epiphyses of the long bones, and curvature of the legs and spine are found in varying degrees in those cases of status lymphaticus which are associated with the rachitic dyscrasia In adults, marks of one time rickets may still be demonstrable, especially such as pigeon-breast, spinal curvature, narrow pelvis, bow-legs, etc.

The blood changes of status lymphaticus are, as has already been said, too indefinite to permit of diagnostic discrimination

Etiology and Relationship to Associated Clinical Manifestations.—We are still in the dark as concerns the etiology of the strange constitutional condition whose morphological characteristics have been portrayed. It is well established that some relationship exists between rachitis and status lymphaticus, and one would be inclined to call the latter the lymphatic form of rachitis were it not that cases are encountered without manifest evidences of rickets, that is to say, we have a non rachitic status lymphaticus. The frequency with which the conditions coexist, especially in infants where changes of rickets retain their prominence, argues for the direct relationship of the two affections, and I am inclined to believe that more exhaustive search, especially such as is comprehended by histological studies of the epiphyseal bone changes, would demonstrate the presence of rachitic lesions in cases of the lymphatic state where none of the coarser anatomical manifestations are to be found. It is, in fact, quite probable that status lymphaticus and rickets of a gross or a microscopically demonstrable grade will be found to be invariably associated. Were this the case we would still be a-field in the question of etiology, since the direct exciting element in the causation of rickets is as yet unknown. Of all the theories, however, the one attributing rickets to an infectious agency seems most plausible, and adherents to this view are rapidly increasing. According to this theory, rachitis is the result of a microbic infection, not necessarily due to a single bacterial species, but to one of several of the pyogenic organisms which act slowly, and which elaborate poisonous products capable of producing the osseous or other alterations found in the disease. The view that rachitis is caused by a slumbering or latent pyogenic infection, like a focus of middle-ear or mastoid disease, and that the gradual or periodic discharge of toxins from this focus induces the rickets, is particularly inviting, and even at the present moment claims some experimental data in its support. If we accept the infectious theory of rickets it becomes easier to reconcile its association with status lymphaticus, for the latter then becomes its lymphadenoid form, in which the various lymphatic structures give a hyperplastic reaction in response to the chronic intoxication. That various forms of lymphatic overgrowth result from infections has long been definitely determined, and at the present moment we witness the tendency to include such pronounced diseases of the lymphatic system as pseudoleukæmia and even leukæmia in the category of infectious diseases. In the face of this tendency it seems entirely reasonable to look to the enlarged lymph nodes, lymph follicles, and swollen spleen of status lymphaticus as the products of a slowly acting latent infection, or to the gradual or periodical discharge of attenuated pyogenic products from a hidden focus of infection.

As to the relations which exist between status lymphaticus and the clinical phenomena associated with it we possess but little information. We have already found that the theory of reflex cardiac paralysis has been admitted to explain the sudden deaths of status lymphaticus, the increased susceptibility of the heart to various forms of irritation being a part of the lowered vital resistance incidental to this constitutional disorder. This hypothesis has been generally accepted, but it still leaves something to be desired in the way of more fully explaining the exact mechanism by which the cardiac paralysis is induced.

The causal relationship between status lymphaticus and such convulsive disorders as spasm of the glottis, eclampsia, idiopathic tetany of infants, and epilepsy is largely conjectural. Escherich, who regards spasm of the glottis (thymic asthma) as one of the syndromes of tetany, attempts to account for these neuroses by an hypothesis somewhat like the following:

If, from analogy with the thyroid, we assume that the hyperplasia of the thymus and its coördinated organs (characteristic of status lymphaticus) is, or may be, the expression of an incomplete or perverted metabolism, the condition (status lymphaticus) might be regarded as a dyscrasia or chronic intoxication, comparable to Basedow's disease or the myxœdema of cachexia strumipriva. The changes in the skin and in blood formation, and especially the phenomena referable to the central nervous system, show a decided similarity, but differences are present quite sufficient to distinguish the two dyscrasias. While the strumous diathesis tends to impair the intellect to the point of imbecility or idiocy, we find, in the case of the hypothetical lymphatic-chlorotic constitution, that a latent irritability of the nervous system exists, which reacts to trifling stimuli, ineffective in the case of ordinary individuals, with spasmodic conditions in various portions of the body. To this is added, especially in severe cases, the fatal tendency to syncope, mostly in consequence of some opportune case further acting harmfully upon the heart.

Galatti directs attention to a peculiarity of status lymphaticus which, in my opinion, is a factor of importance in explaining some of the clinical phenomena, viz., the peculiar predisposition to œdema. This, as Galatti asserts, is shown by the pasty condition of the skin, by the tendency to eczema, and by the occurrence of œdema of the brain. I would add, from my observation upon lymphatic epileptics dying abruptly in a single seizure or from rapid status epilepticus, œdema of the lungs as another of the manifestations; an observation already made by Kundrat in a case of sudden death during chloroform anæsthesia, by Langerhans in the case of his son's sudden death after a prophylactic antitoxin injection, and by Paltauf in at least one of his cases of sudden death. Galatti holds that slight factors like auto-intoxications of various kinds may incite this tendency to œdema into activity. Piedecocq, in his belief that sudden death in infants with hyperplastic thymus is due to increased intracranial pressure resulting in compression of the medulla, is evidently upon the tack taken by Galatti, though he wishes to ascribe the increased cerebral pressure to compression of the great vessels in the neck caused by a backward flexion of the head, aggravating the pressure already exerted by an enlarged thymus.

Whatever its mechanism, I am, from my observation upon lymphatic epileptics and my reflection upon these studies, strongly disposed to the belief that a periodic increase of intracranial pressure, acting either on the exterior or interior of the brain, or on both portions simultaneously, and manifesting itself as a result of the tendency to œdema characteristic of status lymphaticus, is a directly provocative factor of such neuroses as spasm of the glottis, tetany, infantile eclampsia, epilepsy, and the various forms of sudden death incidental to the lymphatic state. According to this view, the clinical phenomena would depend upon the extent and location of the intracranial œdema, or, in other words, upon the portion of the encephalon particularly subjected to pressure. In the event of compression of the external portion of the cerebrum, various convulsive disorders of the motor apparatus are provoked; when the balance of pressure becomes so distributed as to raise the intracerebral tension, other more severe symptoms supervene, ending, in case of pressure upon the floor of the fourth ventricle, in sudden respiratory or cardiac failure. Granting the hypothesis just advanced, we are brought one step nearer the explanation of the *modus operandi* of several obscure neuroses whose kinship has repeatedly been recognized on purely clinical grounds, and whose morbid anatomical association is proven by the establishment of the lymphatic state as a common basis for all. Cheadle's dictum that "laryngismus, tetany, and general convulsions are the positive, comparative, and superlative of the convulsive state of childhood," finds support and elaboration.

Treatment.—Recalling the intimate association of status lymphaticus and rickets, treatment, particularly in its prophylactic phase, is clearly indicated. Measures which are efficient in the prevention or treatment of rachitis are, on *a priori* grounds, destined favorably to influence the lymphatic state, and incidentally to control those disorders which result from these constitutional dyscrasias. While not recognizing the kinship of rickets and status lymphaticus, Gowers, for instance, reached the conclusion that a certain proportion of cases of epilepsy were ascribable to rickets, and he urged the prophylaxis of rickets as a means destined to prevent epilepsy. My studies on epilepsy and its relations to the lymphatic state have brought me to this same conclusion, and I agree with Gowers that the prevention of rickets is a matter of great moment in suppressing epilepsy, as well as in favorably influencing such other neuroses as spasm of the glottis, tetany, and infantile eclampsia. It is out of the province of this article to discuss the means, especially those of a dietary and hygienic nature, advised for the prevention of rickets, or for combating it when once established. These agents, with the medicinal aid ordinarily employed, are rationally indicated in the prevention or treatment of status lymphaticus.

On the supposition that the thymus is the chief anomaly of status lymphaticus and the agent in producing an auto-intoxication, numerous suggestions for the employment of extracts of the gland have been made. Permanently beneficial results have not been recorded in cases in which thymus extract has been administered, and this is likewise true for the thyroid and adrenal extracts. Very recently Mendel, who attributes rickets to disturbance of the internal secretion of the thymus, has reported good results following the exhibition of fresh calves' thymus in doses of one gram for each month of the child's age.

Partial removal of the thymus has engaged the attention of those who adhere to the pressure theory of thymic asthma, and in at least two cases this heroic procedure has been practised. One case reported by König, and quoted by Blake, was a child nine weeks old, which since it was eight days old had suffered from severe attacks of dyspnœa. The thymus was made out to be enlarged, extending to the cricoid in the neck. By means of a transverse incision it was exposed, the cervical portion excised, and the thoracic portion drawn up and anchored by sutures to the fascia over the manubrium. The operation was completely successful in relieving the dyspnœa, and healing was uneventful.

The second case, also reviewed by Blake and reported by Siegel, was a boy of two and a half years, who had been tracheotomized for a sudden attack of dyspnœa. The insertion of an ordinary cannula did not afford relief, and it was not until a tube had been inserted nearly to the tracheal bifurcation that the dyspnœa ceased. A diagnosis of enlarged thymus was made, and the thymus was drawn up and sutured to the fascia over the sternum. Recovery was uneventful, with no recurrence of the dyspnœa. What interpretation to place upon these two cases is uncertain. Whether, for instance, the apparent good results were due to relief of pressure, as König and Siegel believe, or whether due to the extirpation of a portion of the thymus *per se*, or to a changed anatomical relationship of the gland, by which some autotoxic effect was annulled, cannot be decided from two isolated cases. However, these cases are at least suggestive from the standpoint of the surgical therapeutics of status lymphaticus, though it is not probable that such a severe measure as partial extirpation of the thymus will be recommended as a legitimate procedure in any except the class of cases indicated by König and Siegel. In this connection, however, it is well to recall the remarkable results which usually follow the removal of nasopharyngeal adenoids and of hypertrophied faucial tonsils, which, as we have learned, are manifestations of the lymphatic state. After making due allowance for the good effects resulting from the relief of the mechanical obstacles imposed by these enlarged structures, the remarkable change in bodily and facial configuration, and the brightening of the intellect not uncommonly observed in these cases, has suggested to more than one observer the possibility of other far-reaching influences besides those of a mechanical nature. It seems highly probable, indeed, that the removal of the offending lymphatic structures carries with it some deep-seated beneficial effect such as one might imagine to result from the removal of an auto-intoxication. There is certainly abundant evidence to show that the surgical treatment of the enlarged lymphatic structures of the nose and throat is a rationally indicated procedure in the therapeutics of status lymphaticus.

Albert P. Ohlmacher.

Bibliography.

Owing to the confusion concerning the relations of the enlarged thymus to the constitutional disorder, most of the literature bearing upon status lymphaticus will be found under the diseases of the thymus as indicated by such titles as "Hypertrophy of the Thymus," "Sudden Death and Hypertrophy of the Thymus," "Thymic Asthma and Sudden Death," etc.

Therefore, instead of attempting to enumerate the papers in which the anatomical and clinical features of status lymphaticus are more

or less explicitly discussed, the student's attention will be invited merely to the leading articles dealing specifically with status lymphaticus in its different aspects. Even in some of these articles the title refers directly to the thymus:

Rokitansky: Path. Anatomie, Wien, 1842–46. Definitely mentions the lymphatic dyscrasia and plainly points out the coördinate relations of the enlarged thymus to the lymphadenoid hyperplasias.

Virchow: Beiträge z. Geburtsh. u. Gyn., 1872. Discusses the relation of arterial hypoplasia and chlorosis and defines the "lymphatic-chlorotic constitution."

Grawitz: Ueber plötzliche Todesfalle im Säuglingsalter. Deut. med. Wochenschr., No. 22, 1888. Reopens the discussion upon thymic, or, more properly, lymphatic sudden death, and marks what may be called the recent era in the study of status lymphaticus.

Paltauf, A.: Ueber die Beziehung der Thymus zum plötzlichen Tod. Wiener klin. Wochenschr., No. 46, 1889, and No. 9, 1890. Clearly defines status lymphaticus by its morbid anatomical basis, and deals with various forms of lymphatic sudden death.

Pott: Ueber Thymusdrusenhyperplasia und die dadurch bedingte Lebensgefahr. Jahrb. f. Kinderheilkunde, No. 34, 1892. Deals especially with spasm of the glottis and resulting sudden death. The relation of status lymphaticus as the anatomical basis is kept in view.

Nordmann: Ueber die Beziehungen der Thymusdrüse zu plötzlichen Todesfällen im Wasser. Correspdbl. f. schweizer Aertze, No. 7, 1894. As its title indicates, this paper deals especially with lymphatic sudden death in the water. Status lymphaticus in its anatomical and etiological relations is discussed, though the thymus claims most attention.

Kundrat, v.: Zur Kenntniss des Chloroformtodes. Wiener klin. Wochenschr., Nos. 1–4, 1895. The relations of status lymphaticus to fatal surgical narcosis are there elucidated together with a number of original cases.

Escherech: Bemerkungen über den sog. Status lymphaticus des Kindes. Berl. klin. Wochenschr., No. 29, 1896.—*Ibid.*: Tetanie. Traité des maladies de l'enfance, tome iv. Considers the various neuroses of status lymphaticus like tetany, spasm of the glottis, eclampsia, and lymphatic sudden death, and elaborates a theory to explain the association.

Galatti: Zur prognostischen Bedeutung des Status lymphaticus der Kinder. Wiener med. Blätter, No. 50, 1896. Lymphatic sudden death is considered, including a discussion of fatal accidents after antitoxin injections as illustrated by the Langerhans case. Mentions the predisposition to œdema.

Ewing: The Lymphatic Constitution and Its Relations to Some Forms of Sudden Death. New York Medical Journal, July 10th, 1897. An excellent review of status lymphaticus in its different aspects, with a presentation of most of the literature. Especially valuable as being readily accessible to the American student. Apparently the first article in English dealing with status lymphaticus *per se*.

Ohlmacher: Bulletin of the Ohio Hospital for Epileptics, Nos. 1, 2, and 3, 1898–99. Several papers discussing especially the question of status lymphaticus and epilepsy.

Daut: Ueber die Beziehungen des Status lymphaticus zur Diphtherie. Jahr. f. Kinderheilkunde, Heft 2 and 3, 1898. As shown by its title, this paper concerns the relations of status lymphaticus to diphtheria and contains the most exhaustive study of this phase of the subject thus far published.

Klein: Neuere Arbeiten über die "Glandula thymus." Zusammenfassendes Referat. Cent. f. allgem. Path. u. path. Anat., Nos. 16–17, 1898. Though primarily considering the diseases of the thymus, this review cites all of the important papers bearing on status lymphaticus, and reviews them briefly.

Blake: The Surgical Aspects of the Status Lymphaticus. Annals of Surgery, June, 1902. The most recent American paper, the purpose of which is indicated by the title.

STAVESACRE.—(*Staphisagria*, U. S. P.; *Staphisagriæ Semina*, Br.; *Staphisagria*, Codex Med.) The dried ripe seed of *Delphinium Staphisagria* L. (fam. *Ranunculaceæ*).

This seed is derived from a handsome annual or biennial species of larkspur, native of the South European countries, Asia Minor, etc., and also cultivated. The seeds are imported from the south of France and Italy. They were known to the ancients, and for twenty centuries have been used for about the same purpose as at present—killing pediculi and similar vermin.

Description.—About 5–7 mm. ($\frac{1}{5}$–$\frac{1}{4}$ in.) long and nearly as broad, flattish-tetrahedral, one side convex, another small and opposite to a pointed extremity, the edges rather acute; brown, gray-brown, or sometimes blackish, strongly and coarsely reticulate-wrinkled, containing a whitish, or becoming gray-brown, oily perisperm and a small, straight embryo; nearly inodorous; taste very bitter, acrid, and somewhat biting.

Composition.—The seeds contain about twenty-five per cent. of a non-drying fixed oil, and about one per cent. of alkaloids, occurring mostly in the shell, of which the following have been isolated and named: *delphinine*, in fine, large crystals, *staphisagrine*, amorphous; *delphinoidine*, also amorphous, and *delphisine*, in crystalline tufts. Of these, the first is the most important and active, the second least so, while the third and fourth resemble the first, but are weaker.

Action and Use.—Stavesacre is an active and poisonous drug, irritant to the skin and mucous membranes, causing itching, stinging, burning, sneezing, etc., as well as diarrhœa and vomiting. Of the alkaloids, delphinine best represents the drug; rubbed into the skin, this causes local inflammation, on the tongue burning and numbness, in the stomach nausea and distress, and, when absorbed, cardiac and respiratory slowing, diminished spinal irritability, and sometimes mental disturbance. The others resemble delphinine, but are less intense. Delphinine reminds one of both aconitine (to which it is botanically related) and veratrine. Staphisagrine is somewhat peculiar; it is not very active, but appears to resemble curare in its action upon striped muscle.

Neither the crude drug nor its alkaloids are given internally; so its exact action has but little practical bearing. It has from a remote time been employed, either by itself or in ointments or other vehicles, solely for the purpose of killing pediculi and related animal parasites, on man and animals. At the present time it is mostly consumed in veterinary practice, kerosene or petroleum, petrolatum, sulphur, and *Unguentum hydrargyri* taking its place in human medicine. An ointment can be made with twenty per cent. or so of the powdered seeds, or with from one-half to one per cent. of the alkaloid.

Larkspur seeds, the product chiefly of *Delphinium Consolida* L., and produced in Europe, are almost identical in constituents and properties with stavesacre. They were formerly official in the United States Pharmacopœia, and tincture of larkspur is a very popular application for head lice. They are several times smaller than stavesacre seeds, of about the same form, but with sharper angles and markings, and usually of a jet black color. *Henry H. Rusby.*

STEAMBOAT SPRINGS.—Routt County, Colorado.

Post-Office.—Steamboat Springs. Hotels.

Access.—Viâ Denver and Rio Grande Railroad to Walcott, thence by stage, a twelve hours' ride to springs. Also connected by good mountain roads with Laramie City, Wyo., and with Georgetown, Dillon, Glenwood Springs, Hayden, and other points.

The town of Steamboat Springs is located in a charming valley in northwest Colorado, just over the main range of the Rocky Mountains and near the headwaters of the Yampa River. The site is upon a bend of the Yampa, where, from its northerly flow, it turns sharply to the west. The mountain range here follows the contour of the river, lifting its lofty summits, covered all summer with their ever-melting but never-melted snow, on two sides of the valley to the north and east. Thus is formed a natural basin, sheltered on the side toward the north by its mountain bulwark, leaving its southern slope open to the rays of genial sunshine. Three large mountain streams—Soda Creek, Crystal Brook, and Spring Creek—rise at different points along the curve in the mountain range, and, converging as they flow down, join the Yampa on the town site. These streams furnish a never-failing supply of pure water, and, with a group of sixty varieties of hot, warm, and cold mineral springs, make this valley one of the most remarkable natural watering-places in the world. The first settlement was made in the valley in July, 1874, by Mr. James H. Cranford, the present manager of the springs. Since that time a flourishing town containing churches, schools, libraries, banks, newspapers, and other adjuncts of civilization, has sprung into existence. The town and vicinity offer many attractions to the enterprising settler, as well as to the tourist, the sportsman, and the invalid. The climate during the open season—*i.e.*, from April until late in December—is ideally temperate, clear, balmy days and cool nights being the rule. The springs, one hundred and forty in number, yield an exhaustless supply of water, but they have not been fully developed yet. They range in temperature from 40° to 103° F., but none of them appears to have been subjected to a complete analytical examination. Among the prominent ingredients are soda, magnesia, iron, and sulphur. The waters have been found useful in rheumatism and skin diseases, and were resorted to by the Indians for many years before the appearance of the pale face in this region. A large bath-house with swimming pool and numerous bath-rooms has been built to utilize the water from the hot springs. *James K. Crook.*

STEAPSIN. See *Pancreas*.

STEATOMA.—By many writers this term is used synonymously with lipoma; but by others it is applied to a hard variety of this tumor, in which the fat cells are of small size and the amount of connective-tissue reticulum relatively large. Such tumors resemble bacon in their gross appearances and have been designated by German authorities "Speck-tumor." In the majority of cases such tumors arise from the atrophy of the fat cells in any ordinary lipoma, and the characteristic appearance and consistence of the growth are, therefore, to be regarded as the result of secondary changes. Other writers apply the term steatoma to any variety of fibrolipoma, and the designation has even in a few instances been transferred to fibromata. By other writers still, atheromata, sebaceous cysts, and dermoid cysts, as well as retention cysts of varying origin containing fatty or pultaceous material, are also called steatomata. The varied and indefinite use of the term would appear to offer good reasons for its abandonment. *Aldred Scott Warthin.*

STERIFORM. See *Formaldehyde*.

STERILITY IN THE MALE. See *Sexual Organs, Male, Diseases of.*

STERILITY IN WOMEN.—

"If a woman do not conceive, and wish to ascertain whether she can conceive, having wrapped her up in blankets, fumigate below, and if it appear that the scent passes through the body to the nostrils and mouth, know that of herself she is not unfruitful."—*Hippocrates, Aphorism 59.*

Sterility (from στειρεος, "barren") in woman is an inability to conceive or bring forth a living child. Inability to conceive is called absolute sterility; inability to complete gestation is denominated relative sterility. It may be congenital and due to some insuperable error of conformation, or it may be acquired as the result of some local or general barrier. When a woman has never been able to conceive it is called primary sterility; when she has conceived one or more times, but is unable to conceive again, it is called secondary; when she can conceive, but is unable to carry the child to full term, it is called comparative sterility.

Prior to puberty, during lactation, and after the menopause, sterility is physiological.

The generally accepted ratio of sterility among civilized nations is eleven per cent. In primitive conditions and rural communities it is much less than in complex civilizations and in cities. Rich diet and luxury seem to be inimical to fertility; spare diet and poverty appear to increase fecundity. Sterility is rapidly increasing in the United States, especially in native-born white women. Prior to 1850 it was only two per cent. In 1900 it was twenty per cent. Among foreigners in the United States it is thirteen per cent. It is greater in the United States than in any country except France (Engelmann).

The fecundity in some parts of Europe is eight to a family; the average is five to a family. In the United States there are only two children to a family. In women who are college graduates the ratio is 1.6 to a family.

The causes of this increase of sterility are many. They are moral more than physical. Distaste for the burdens of maternity, from motives of ease and on account of the demands of society, is a prominent cause. The prevention of conception and the production of abortion are increasing ominously. The sin of Onan is making its moral and nervous wrecks. The abomination which Mme. De Staël describes as "a cobweb as regards protection and a bulwark against love" is ever more frequently employed. The marital approach is often guarded by the paraphernalia of the brothel. The secular and religious press is besmirched by advertisements of so-called emmenagogues; of sundry ingenious syringes, and other devices to thwart nature in the procreation of the species. These latter causes for sterility must be taken up by the political economist and prevented by legislative enactment. The increase of sterility from these reprehensible immoral practices, if not restricted, will be an occasion for national alarm. Mathews Duncan says:

"A healthy woman living in wedlock all of her child-bearing life under the most favorable circumstances for natural procreation, should have a family of ten. Women, under such circumstances, bearing fewer than ten, are relatively sterile, and the sterility is inversely as the number." He found the mean interval between marriage and the birth of the first child to be seventeen months; and that the likelihood of conception proportionately decreased thereafter. Only twenty-five per cent. of women bear the first child after four years of wedlock. A woman, therefore, who has been married three years without conception, and where no means to prevent it have been resorted to, may be presumed to be sterile.

Simpson out of 1,252 marriages found 1 in 8.5 unfruitful. Ansell, in the British peerage, found 1 in 6½. Engelmann among college graduates, 1 in 3½. Duncan says the average for Great Britain is 1 in 10, which may be taken as the general average.

In all sterile matrimonies it must be borne in mind that the male may be at fault. Gross, in 192 instances, found the male to be at fault in 16⅔ per cent. Kehrer, in 40 cases, found 31.5 per cent. Emil Ries estimates 30 per cent. Vedder, of Christiania, in 310 examples, found 70 per cent. due to the male, either to impotency or azoospermia. He includes infection of the wife by gonorrhœa, but this should not be included in an estimate of essential male sterility. Gonorrhœa in the male, resulting in double epididymitis and occlusion of the vas deferens, is the greatest factor. Surgical relief from this asexualization of men is much to be desired.

Assuming that from one-third to one-half of all childless marriages are due to the male, the woman should not bear the reproach until a microscopical examination of the semen of her partner is made, to determine the absence or presence of living, healthy spermatozoa.

CAUSATION.—Any cause which prevents the meeting of virile spermatozoa with a perfect ovule in the genital passages of the woman and their further fixation and retention in the uterus until gestation is completed, will result in sterility. These causes may be generalized as follows:

I. Incapacity for perfect copulation.

II. Inability of spermatozoa to enter the uterus, or anything that may prevent the occurrence of fixation after insemination of an ovule.

III. Imperfect ovulation or tubal impediments.

IV. Failure of the uterus to retain the embryo.

V. Sexual incompatibility.

VI. General diseases or diatheses.

Anatomically, these causes are found to be malformations or pathological conditions of (*A*) vagina; (*B*) uterus; (*C*) Fallopian tubes; (*D*) ovary.

(*A*) *Vagina.*—Absence, incomplete development or atresia of the vagina; imperfect hymen and congenital narrowness or shortness of the vagina; adherent labia minora; abnormal communication between the vagina and the bladder, rectum, or urethra; vicious insertion of vagina; double vagina, transverse hermaphrodism; vaginismus or dyspareunia from any cause; laceration or relaxation of the perineum; vaginitis, genital fistulæ; elephantiasis and tumors of the pudenda; prolapsus of uterus and vagina.

(*B*) *Uterus.*—(*a*) Cervix: Atresia or stenosis of the os or cervical canal; hypertrophy of the whole or of one of the segments of the cervix; elongated cervix; contracture of cervical canal from injudicious use of caustics or improperly performed trachelorrhaphy; endocervicitis.

(*b*) Corpus: Flexions, or versions; neoplasms; inflammation of the endometrium; infantile uterus, uterus unicornis or bicornis; non-development of cavity from arrested development of Müller's canals; subinvolution, hyperinvolution, or atrophy after labor or curettage.

(*C*) *Fallopian Tubes.*—Congenital absence or impermeability; closure of fimbriated extremities by gonorrhœa or other inflammation; salpingitis; destructive secretions; inflammatory impermeability of canal; peritoneal adhesions causing mechanical flexures; occlusion due to pressure of new growths.

(*D*) *Ovary.*—Absence, or imperfect development; acute or chronic oöphoritis; cystic degeneration; neoplasms; prolapsus of ovary; embedding adhesions.

I. Incapacity for Copulation.—The abolition of this function, which is usually essential for insemination, is, if permanent, an absolute bar. Insemination is not dependent upon sexual desire or sexual pleasure. It may occur in totally frigid women, or in those who have a positive disgust for the act. Pregnancy may occur if the genital passages are clear, when copulation is performed by force, as in rape, under anæsthetics, alcohol, or other drug narcosis. The deposition of semen on the pudenda, without intromission, has been known, indubitably, to have produced conception.

However, in sterility, any abnormality about the vulva and vagina should be detected. Imperforate hymen, adhesion of the labia, and atresia of the vagina are quite obvious causes.

Vaginismus, by its spasmodic contracture of the sphincter of the vagina, may incapacitate the woman for the marital relation. Dyspareunia, from vulvitis, vulvar hyperæsthesia, urethral caruncles, and pelvic inflammatory diseases, may interfere with coitus to such an extent as to preclude conception, although the woman is potentially fertile. Due care in eliciting the history and making the examination will disclose one or more of the many causes of this painful intercourse. An unusually short vagina may not retain the semen, or it may be violently evacuated by involuntary vaginismus of the upper part of the vagina (Storer). Relaxations of the vulvar orifice from laceration of the floor of the pelvis may also allow the semen to escape prematurely. The extreme acidity of a profuse leucorrhœa from a vaginitis is destructive to the spermatozoa, which require an alkaline medium.

II. Inability of the Spermatozoa to Enter the Uterus, or the Presence of Some Condition which does not Permit Fixation to Occur after the Insemination of an Ovule.—Formerly it was supposed that flexures of the uterus at or near the cervix offered a mechanical obstruction to the entrance of the spermatozoa; but it is now generally believed that if the obstruction, so called, will allow the exit of the menstrual flow, it will also allow the entrance of the spermatozoa. The sterility in flexions of the uterus are due to the attendant endometritis, the discharges from which may mechanically wash away or destroy the spermatozoa. Furthermore, the altered state of the uterine mucous membrane, in cases of this nature, will not permit fixation to occur.

While atresia or stenosis may prevent entrance of seminal fluid, the thick, tenacious plug of mucus, in cases of endocervicitis, more often acts as a barrier.

Conicity with elongation of the cervix prevents insemination because the cervix does not rest in the pool of semen bathing the posterior fornix of the vagina. The same difficulty exists when the cervix is either anteflexed or retroverted; in other words, the spermatozoa are shut off from the opportunity of entering the uterus by their ciliary movements. In uncomplicated retroversion a restoration of the uterus to its normal position may lead to the occurrence of pregnancy after years of unfruitfulness.

Anteflexion, associated with dysmenorrhœa, is often found in barren women. Sims' observation, that nearly half of the women with dysmenorrhœa are barren, means that the barrenness usually depends upon some pathological process causing the dysmenorrhœa. In anteflexion the pathology is that of an atrophic endometritis, usually associated with imperfect development. The painful menstruation is dependent upon the faulty desquamation of the endometrium and the resulting coagulation of the blood. In these cases of flexion it is not, as was formerly taught, the obstruction to the outflow which causes the dysmenorrhœa, but rather the associated endometritis; for when the latter is cured, as it may be by divulsion and curettage, the dysmenorrhœa disappears. Such a cure of the endometritis, furthermore, means the reproduction of a new and healthy endometrium, and so favors the cure of the sterility.

Fibroid tumors were found to be the cause of sterility in 18.3 per cent. (III). Here, again, we may refer the sterility to the hypertrophic endometritis which accompanies the growth of these tumors; for the ovum cannot effect an attachment to the wall of the uterus during the progress of such an inflammation. In brief, then, whenever the uterus is at fault in a case of sterility, it will be safe, in the majority of instances, to attribute the cause of such sterility to an endometritis.

III. Imperfect Ovulation and Tubal Impediments.—Absence and faulty development of the ovary and oviduct are rare without congenital absence or malformation of some other part of the genital apparatus. Arrest of the function of the gland may ensue from acute or chronic inflammations, from cystic degenerations that are complete and bilateral, and also from obliteration of the glandular structures by new growths.

Inflammatory sequelæ of infections ascending to the peritoneum are the most important causes of sterility arising in the adnexæ. The ovary may be prolapsed or placed beyond the reach of the infundibulum, or it may be surrounded with inflammatory exudate so that extrusion of an ovule is impossible. The tubes may be, as seen very commonly in abdominal work, glued up at the abdominal ostia by inflammatory exudate. The fimbriæ may be so distorted that they cannot come in contact with the ovary. Intraperitoneal bands of adhesions sometimes cause a narrowing of the lumen of the Fallopian tube. The endosalpinx, after inflammation, is commonly desquamated of its ciliated epithelium. The spermatozoon cannot make its way to the ovary, nor the ovule to the uterus. If perchance they should meet and fertilization ensue, tubal pregnancy is likely to occur. The tubes, after serious inflammation, may remain permanently occluded.

Any one or more of the conditions enumerated above are thus seen to be potent in the production of sterility by interference with ovulation and with the transit of the ovum. They may result from clinically mild infections, which, after resolution has taken place, may leave the patient, except as regards the sterility, in good health.

The comparatively recent recognition of the ravages caused by gonorrhœa in woman affords strong confirmation of Tait's contention that practically all women who have suffered from gonorrhœal infection of the tubes are sterile. Witness the notorious sterility of prostitutes, which is largely due to this cause. The point of greatest importance is to determine what proportion of these patients are hopelessly so, and what proportion may be relieved by conservative surgical operations. It is for the future to determine whether laparatomy is indicated for the cure of sterility alone. The lesions resulting from gonorrhœa comprise perhaps the largest group of the mechanical causes of sterility.

IV. Failure of the Uterus to Retain the Embryo.—This particular one of the procreative phenomena does not come under the scope of this inquiry. Habitual abortion, however, should always arouse the suspicion that one or both parents are infected with syphilis; and if other facts seem to bear out this view, active antisyphilitic treatment should be inaugurated. The results of such treatment are often very satisfactory.

Early abortions are very frequent. Ninety per cent. of child-bearing women abort once or oftener. One out of twelve pregnancies is said to end in abortion. It may be caused by trauma, by emotional violence, or by pelvic and general disturbances. The underlying cause may reside in either the father, the mother, or the fœtus.

Endometritis and laceration of the cervix are perhaps the most frequent, curable, local causes.

V. *Sexual Incompatibility.*—There is an intangible, unknowable something which causes sterility in the apparent absence of any pathological condition whatever, and this something, for want of a more exact term, we call incompatibility. Husbands and wives, each of whom has previously been fruitful with another mate, or each of whom at some subsequent period becomes fruitful when joined to another mate, will live together for years and yet will have no children. History furnishes the notable example of Augustus and Livia, and the well-known instance of Napoleon and Josephine. A satisfactory explanation is the despair of science. This form of infertility has been noticed in the breeding of animals.

VI. *General Disease, or Weakness.*—Obesity, with its attendant anæmia, is often the cause of sterility. It is presumed that the ovule is imperfectly matured. The rheumatic or gouty diathesis probably acts by nutritional defects, as does syphilis. Chronic alcoholism sometimes is causative through depreciated vitality. Unhygienic occupation and excessive wear and tear may prevent conception. A depressed state of the nervous system may suspend ovulation temporarily; hardships, grief, great mental anxiety, shock, unhappy marital relations, are mentioned as causes. Neurasthenia and certain nutritional neuroses render conception unlikely.

Tuberculous subjects are not necessarily infertile. Gestation greatly increases well-being, but parturition and lactation render the victim susceptible to the ravages of the disease. Prolonged lactation grants the woman partial immunity from conception, and is frequently used for that purpose, at the expense of both mother and child.

Prognosis is notoriously uncertain. Removal of palpable causes gives a fair prospect of success, sufficient to justify any reasonable effort, but a full statement of the improbabilities should be made to the patient. Sometimes when every discernible obstacle has been removed, sterility still persists. One should not, however, give a positive opinion that the case is a hopeless one unless some malformation presents an insuperable bar.

Conception has been known to occur under most unfavorable circumstances. Pregnancy constitutes a serious complication in fibroid tumors, and sometimes in carcinomata. It has occurred in cases of vesico-utero-vaginal fistula. Koeberle's remarkable case of abdominal pregnancy occurring through a small fistula, after vaginal hysterectomy, where a portion of the ovary was left, is unique.

Treatment.—A minute and painstaking search for the cause or causes of this condition is essential to any therapeutic attempt. If no appreciable cause is found in the woman, or before any elaborate plan of treatment is instituted if the cause is found, the presence and viability of spermatozoa should be determined. Men are loath to have an examination made that may fix the responsibility on them. In order to obtain a specimen for examination an ingeniously framed excuse, if necessary, may be made to the woman for an examination shortly after coitus.

Male potency being assured, the physician should then proceed to correct or remove any and all abnormalities possible in the genital canal, and also to remedy any systemic faults which may exist. Vulvar or vaginal impediments should be removed and the copulative tract put in a healthy state. Displacements of the uterus are to be corrected by appropriate means. Lacerations should be repaired, if necessary.

General hygienic measures are to be employed where necessary, with especial attention to anæmia and the diatheses. Higher education is unpropitious for a race of mothers. Great sexual moderation should be enjoined. Abstinence for a period of months, or, if need be, a complete separation for the same length of time, is often followed by conception. Such a separation gives an opportunity for a spontaneous cure of certain slight pathological states, and affords a much-needed sexual rest. Hyperinvolution and ill-developed uteri are treated by intra-uterine galvanism. Great persistence is required in this and all other treatment for sterility.

The former practice of treating an atrophic endometritis, in anteflexion, by simply dilating the cervix has now given place to divulsion of the cervix and subsequent curetting. This plan of treatment is applicable to the majority of cases of endometritis which complicates so many pelvic disorders and upon which sterility so frequently depends. The results obtained are quite satisfactory. Excessive acidity is overcome by alkaline injections before congress.

In the operative treatment of tubal and ovarian disease causing or associated with sterility, conservative surgery is indicated wherever possible and has yielded very happy results in some instances. When child-bearing is desired, the surgeon is justified in exercising much latitude in saving and repairing structures. The justification in invading the peritoneum for tubal sterility unaccompanied by symptoms of disease, is an open question. Goffe has operated four times upon the uterine adnexa through the vagina for the uncomplicated symptom of sterility, and has been rewarded by living children in three of the four cases. Colpotomy is quite as safe now, from a surgical standpoint, with asepsis and expertness, as many of the recognized operative methods on the uterus for sterility were three decades ago.

The frequent cure of the associated sterility, while incidental, has been observed by every operator who has done conservative operations on the internal organs of generation. The following list of conservative procedures mentioned by Kelly will indicate the many checks to conception which might be removed:

1. The release of adherent tubes.
2. The opening or resection of closed tubes.
3. The emptying, cleansing, and sterilization of inflamed tubes.
4. The amputation of diseased tubes.
5. The exsection of diseased or of strictured tubes.

Conservative operations on the ovaries comprise puncture or excision of a small cyst, resection of diseased portions, and release from embedding adhesions. A prolapsed ovary should be sewn back on top of the broad ligament and in relation with the infundibulum.

Before deciding upon an intrapelvic operation for the relief of certain pathological conditions, all the facts should be plainly set before the patient and her husband, in order that they may determine intelligently whether they are willing to incur the discomfort and danger, though slight, of an operation, the result of which is more or less problematical.

Artificial Conception.—This ingenious thought of Sims had for its basis the mechanical obstruction, in the cervix, to the further advance of the spermatozoa. It may be asserted that wherever this passage is sufficiently patulous to allow the nozzle of a syringe to be introduced for purposes of artificial impregnation, the spermatozoa are likely to effect an entrance unaided.

Of the fifty-five efforts made by Sims in two years only one resulted in conception, and that ended in an early miscarriage. A few other cases have been occasionally reported, but the procedure has never had the sympathy of the profession and has practically been abandoned.

Aside from the economic consideration of the importance of sterility to society, it must be borne in mind that it may be the cause of unspeakable disappointment and sorrow to the babeless bosom, and the mother-love will cry out in despair, "Give me children or I die."

William D. Haggard.

STERNUTATORIES, or errhines, are substances which, when applied to the nasal mucous membrane, cause sneezing and increased secretion. Properly speaking, there is a distinction between the two terms, errhine being used to denote an agent which increases the nasal secretions, while a sternutatory causes sneezing only. But as the act of sneezing is almost always accompanied by increased secretion, the distinction between the two classes of remedies is practically without a difference.

In former times sternutatories were much more commonly employed than they are at present, and the older writers were wont to lay great stress on the efficacy of these agents in the treatment of many apparently dissimilar conditions. Their use was recommended (1) to restore suspended respiration; (2) to effect the expulsion of foreign bodies from the air passages; (3) to increase the secretion of the nasal mucus or of the tears, or to expel accumulated mucus from the sinuses; (4) to awaken the action of the encephalon, restore sensibility, or excite uterine action. At the present time remedies of this class are out of fashion, and the only applications to which they are put are to excite sneezing for the sake of the pleasurable sensations that it causes, to increase the nasal secretions in the dry stage of coryza, and to clear the nasal passages and the adjacent sinuses of accumulated mucus. It is possible, however, if the present tendency of attributing many and diverse morbid conditions to the score of nasal reflexes should prevail, that future generations will restore the sternutatories to their ancient rank among the most prized of therapeutic agents.

The list of substances which have been employed at one time or another for the purposes above enumerated is as long as the moral law, and embraces nearly every drug which can be reduced to a fine powder, and even many gases, such as ammonia. To enumerate only a few of them, we have rosemary, lavender, peppermint, spearmint, white and black hellebore, stavesacre, mustard, euphorbium, betonica, ginger, iris, the peppers, calomel, bismuth, the alkaline carbonates, ipecac, tobacco, sweet marjoram, and a host of others. At present this list is practically restricted to half a dozen substances, the chief of which are tobacco, ipecac, veratrum album, quinine, camphor, and cubebs. Tobacco snuff is seldom employed now, except as a luxury, but the others just mentioned enter, one or all, in varying proportions, into the composition of the different catarrh snuffs prescribed by physicians or sold as proprietary remedies.—*From the first edition of the* HANDBOOK.

STETHOMETER. *See Respiration.*

STETHOSCOPES.—HISTORICAL SKETCH.—The credit of having invented the stethoscope has been variously attributed to Hippocrates, Bayle, Hook, Laënnec, and others. It is certain, however, that Laënnec was the first to make the idea practically useful. He hit upon it accidentally, by using a roll of paper which he was holding in his hand. His first instrument was a cylinder of paper compactly rolled and kept in shape by paste. The stethoscope subsequently adopted was a cylinder of wood an inch and a half in diameter and a foot long, perforated longitudinally by a bore three lines wide, and hollowed out into a funnel shape at one end to the depth of an inch and a half. A plug of wood fitted into this hollowed extremity with a perforation through it of the same diameter as that of the rest of the tube. This was used in auscultating heart sounds. It was discarded in stethoscopes made at a later date. The instrument was made in two sections for convenience of carrying. Piorry introduced a more slender instrument, with ivory cap, and later this was altered and made of wood only. An instrument in which the pectoral end was trumpet-shaped was devised by Dr. Williams, of London, about 1843. Since then a large number of monaural stethoscopes have been devised, and descriptions of them are to be found scattered through various medical publications. They have been made of metal, wood, hard rubber, papier-maché, and other materials, used either alone or in combination. Most of these stethoscopes are hollow, the bore of the tube being pretty uniform throughout, except at the pectoral extremity, where it is expanded and bell-shaped. Solid wooden stethoscopes have also been devised, but these are more especially useful in conveying percussion sounds when the method of auscultatory percussion is practised. The monaural instruments do not differ from one another in any important particular. A few are combination instruments, having a percussor and pleximeter attached, or a clinical thermometer, a female catheter, etc., hidden away in them. Among others who have devised monaural stethoscopes may be mentioned Quain, Stokes, Arnold, Barclay, Elliottson, Dobell, Loomis, Burrow, Clark, Cammann, and Ferguson.

FIGS. 4487, 4488, AND 4489.—Monaural Stethoscopes.

M. Landouzy, of Paris, in 1850, constructed a stethoscope with a bell-shaped chest-piece, with a number of flexible tubes attached, by which several observers at once could auscultate. A single tube was designed for each person, but by the use of two tubes it became a binaural instrument. It was necessary to hold the tubes in the ears by the hands, and it was not found to be of much practical use. Many years previously Dr. Williams, of London, had been accustomed to use a binaural stethoscope made of two metal tubes attached to the bell of an ordinary stethoscope, and with flat ear-pieces. This conveyed sound with increased intensity, but was inflexible, clumsy, and awkward of application. The double stethoscope of Dr. Leared, shown in the Great International Exhibition of 1851, was a great improvement. It is made entirely of gutta percha. The two tubes are attached at one extrem-

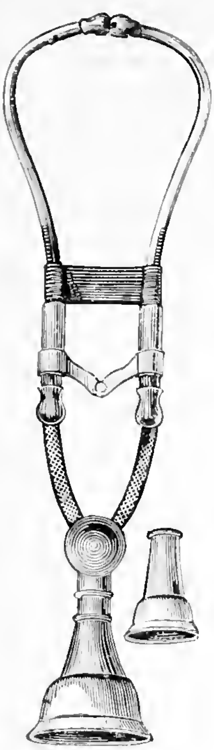

Fig. 4491.—Cammann's Binaural Stethoscope.

ity to a bell-shaped chest piece, and at the other to ear pieces similar to those of the monaural stethoscope. These tubes being separated and applied to the ears, exerted a certain amount of pressure by their own elasticity. To use this instrument ordinarily in practice, however, would require three hands, one for each ear-piece, and another to manage the pectoral end. In 1851 Dr. Marsh, of Cincinnati, patented a double stethoscope. This had a membrane stretching over its objective end, and two gum-elastic tubes leading from the chest piece to the ears. In this instrument the ear-pieces were inconvenient, and the sounds conveyed were muffled and confused. These circumstances rendered it of little value.

Dr. G. P. Cammann devised a binaural stethoscope which, after considerable labor and expense, was perfected in 1852. He was familiar with the instruments of Landouzy and Marsh, and his stethoscope, therefore, was not a new invention, but was, and is now, the best instrument of the kind devised. It is light, durable, easily carried, and a good conductor of sound. The attachment of a rim of soft rubber to the chest piece, as devised by Dr. Snelling, is of advantage in some cases in applying it more closely to the inequalities of the chest. Oval chest-pieces are also made, which enable the end of the stethoscope to be pressed into the intercostal spaces. In most of the instruments now made the rubber band which served to draw the two tubes together is replaced by a spring. In the latest improvement the spring is placed in the screw which binds the tubes together (Fig. 4495).

A considerable variety of flexible stethoscopes are now in use. The credit of having first used one is probably due to Dr. Pennock, of Philadelphia. They may be generally described as consisting of a chest-piece, long flexible rubber tubes, and round ear-pieces. The ear-pieces are held in place either by being firmly pressed into the meatus, or by a spring passing over the head or under the chin. A flexible stethoscope was devised by Mr. Brown, in which the ear-pieces are oval. When placed in the ear, with the long diameter vertical, they are said to remain readily in position. The differential stethoscope of Scott Alison is similar in mechanism to Cammann's, but has two chest pieces, one for each ear, enabling the sounds from different regions of the chest to be conveyed to the two ears at the same time. The hydrophone is another instrument devised by Alison. It consists of an india-rubber bag about the size of a large watch and filled with water. Another inventor had previously constructed a wooden instrument filled with water, but it was not practically useful. Alison found that when water was interposed between two conducting media, sound was conveyed to the ear with increased intensity. The hydrophone may be employed as an instrument by itself, or in aid of the stethoscope.

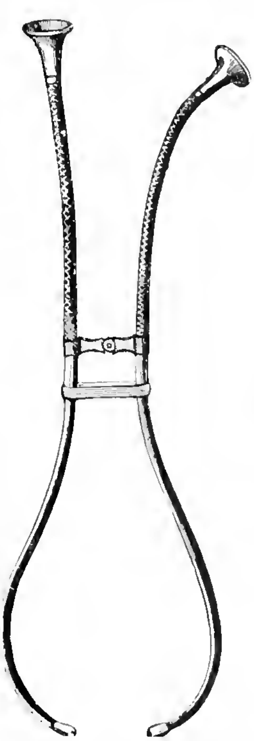

Fig. 4492.—Scott Alison's Differential Stethoscope.

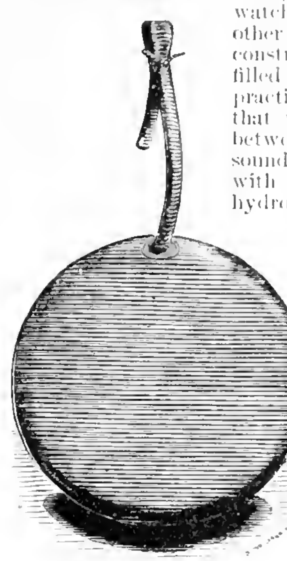

Fig. 4493.—Alison's Hydrophone.

Dr. McBride has devised for use in auscultatory percussion a solid binaural stethoscope of hard rubber, with chest piece sufficiently small to fit in the intercostal spaces. Dr. Constantin Paul devised a stethoscope with two flexible tubes leading to the ears, and a hollow chamber in the chest-piece connected with a rubber bulb by a long flexible tube. If the air in the hollow chamber is exhausted the instrument is held firmly against the chest. A modification of the chest-piece of Cammann's binaural stethoscope, which can be screwed on in place of the usual chest-piece, has been devised by the writer. In the pectoral end is an air chamber, which is completely closed by pressure against the chest. Connected with this chamber by a small tubular opening is a rubber bulb, through which the sound-conducting tube passes. By pressure upon this bulb, when the instrument is held in position, the air is exhausted in the hollow chamber and the stethoscope is held firmly to the chest wall.

Dr. Heineman, of New York, has devised an attachment to the binaural instrument, in which, by an admirably arranged piece of mechanism, the stethoscope is held firmly against the chest by means of a metal rod extending from the chest-piece to the chin, and both hands are left free.

Dr. T. O'Kelly has devised a similar arrangement of a metal rod surmounted by an india rubber cushion upon which the forehead rests, thus enabling the stethoscope to be held firmly in position.

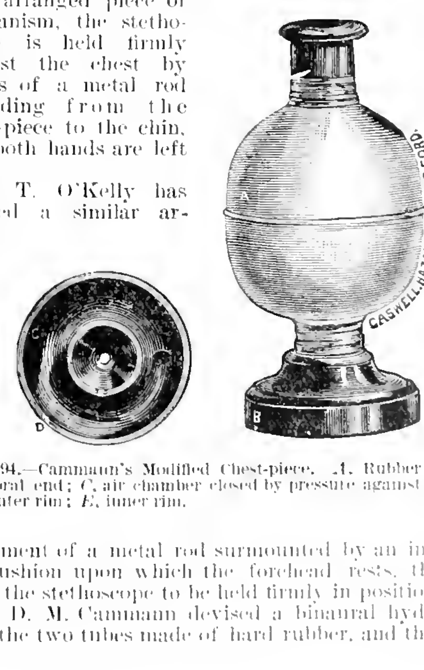

Fig. 4494.—Cammann's Modified Chest-piece. *A*, Rubber bulb; *B*, pectoral end; *C*, air chamber closed by pressure against the chest; *D*, outer rim; *E*, inner rim.

Dr. D. M. Cammann devised a binaural hydrophone with the two tubes made of hard rubber, and thin hard-rubber caps at the aural extremities. The pectoral extremity is covered by a diaphragm of soft rubber, and the instrument is filled with water by means of a faucet. The chest-piece has been already described as a modification of the ordinary binaural stethoscope, and is held firmly against the chest, leaving both hands free. It is intended for use in practising auscultatory percussion.

An instrument has been devised by Dr. Solis Cohen for intrathoracic auscultation. It consists of a rubber tube attached to the binaural stethoscope, and there is a diaphragm of gold-beater's skin in a rubber capsule intervening between the two. The rubber tube passes down the œsophagus.

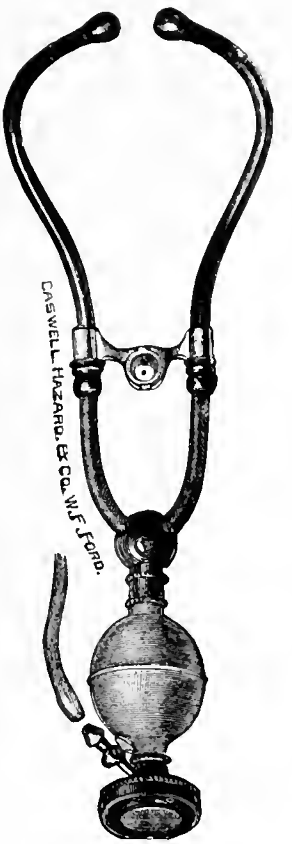

FIG. 4495. — Cammann's Binaural Hydrophone.

Dr. Bowles has devised a chest-piece which can be attached to the binaural stethoscope. It essentially consists of a diaphragm of hard rubber covering the chest-piece, which vibrates and transmits the vibrations to the instrument. It is claimed that with it sounds can be heard more distinctly.

The phonendoscope is an instrument in which there are two diaphragms with an air chamber between, and from the centre of the outer diaphragm a small rod extends, the end of which presents a small surface and, when pressed against the chest, conveys vibrations to the diaphragm.

Both of the instruments last mentioned are patented, and are made by Pilling & Sons, Philadelphia.

In addition to those already described, a number of stethoscopes have in the past ten years been put on the market. They embody no new principle and, so far as the writer is aware, do not convey sound better than the older stethoscopes, when the latter are properly constructed.

CONSTRUCTION OF STETHOSCOPES.—The rules for the proper construction of stethoscopes cannot, in the present state of our knowledge, be formulated with scientific exactness; nevertheless, a knowledge of the laws of acoustics, and of the results of the experiments of others, will aid us in constructing instruments less faulty than many of those now in use. In selecting a material, one should be chosen that, as far as possible, is light, durable, and a good conductor of sound. For the monaural stethoscope nothing has been found better than a light, firm, vibrating wood like cedar. The fibres should run in the direction of the length of the stethoscope. Mahogany, deal, and limewood answer well, but the heavier woods, as oak, beech, lignum vitæ, and boxwood, are inferior and deaden the sonorous vibrations of the bodies upon which they are applied. The quality that makes wood desirable is the same that applies in its use in violins, in sounding-boards for churches, and in the walls of concert-rooms. Other materials, although inferior, are good conductors of sound. Ebonite, a preparation of india-rubber, has the advantage of being light and durable, and easily moulded into shape. The metals, horn, papier-maché, gutta-percha, and ivory are good conductors, and have all been used for this purpose. Hollow stethoscopes are most desirable, as some sounds are conducted best through the solid walls, while others are transmitted most perfectly through the enclosed column of air. The latter is the case with the aërial sounds of the chest, the solid wall of the stethoscope acting as a sounding-board, receiving and transmitting the weakest vibrations. In the practice of auscultatory percussion, a solid wooden stethoscope or the binaural hydrophone is most useful, as sounds produced in solids are best conducted through homogeneous media; but even in this case the ordinary hollow instrument will usually be found to convey sound with sufficient intensity for all practical purposes. The bore of the stethoscope and the hollow in the chest end should not be too large, else there will be caused a confused reverberation of sound; nor should the wall of the stethoscope be of great thickness, both on account of superfluous weight and because the weaker vibrations are thereby checked. It is best that the stethoscope should be of one material throughout and in a solid block. This is not essential, however, and in the binaural instrument is not possible. Theoretically the breaking of continuity, by having it in several pieces, would impair the conducting power; but practically the difference is found not to be as great as might be expected. Flexible stethoscopes, in which the tubes are of soft rubber, or of wire covered with some pliable material, are useful in some cases, but the sounds are modified by reverberation, especially when the tubes are long and with large hollows. The length recommended by Laënnec was one foot divided in two for convenience of carrying. This is unnecessarily long, and six inches is now the usual length. The length of the binaural instrument, from ear to chest-piece, varies from ten or twelve to sixteen or seventeen inches. Most of the binaural instruments have two chest-pieces, one small and narrow, the other trumpet-shaped, which can be screwed on at pleasure. The modified chest-piece may also be used, and can be screwed on in the same way. The smaller end can localize sounds best, and is easier of application to the chest; the larger is more useful in examining the chest rapidly. The edges should not be too sharp, but rounded off both toward the circumference and toward the centre. The ear-piece of the monaural stethoscope ought to be large enough to cover the concha and to close the external meatus. It may be flat, but the most convenient form is with a depression between the circumference and the centre, the latter being considerably elevated. The binaural instruments have small circular knobs, which should not be too large nor too small. If too large, they do not fit closely and allow external sounds to enter; if too small, they cause discomfort by pressure. No instrument will suit all ears, and a stethoscope should be fitted to the ear as a shoe is to the foot.

VALUE OF THE STETHOSCOPE.—In considering the value of the stethoscope it is taken for granted that the instrument used is reliable, and that the auscultator knows how to use it. Some skilful auscultators advocate its continual use; others, equally skilful, advise that it be used only occasionally. The cause of this difference of opinion probably lies partly in difference in the acuteness of hearing and the extent of the training of different observers, and partly is a matter of habit. That the habitual use of the stethoscope does after a time render the sense of hearing less acute to the sounds heard over the chest, in immediate auscultation, is, I think, an undoubted fact. Yet the stethoscope is a valuable instrument, and although it is not always needed, often we cannot attain to a full knowledge of a case without making use both of mediate and of immediate auscultation. Often a doubtful or half-heard sound has been clearly brought out and appreciated by the use of the stethoscope; but still oftener, I think, has a sound scarcely suspected with the stethoscope been made evident by the immediate application of the ear. It requires some practice to become accustomed to the use of the stethoscope, especially to that of the binaural instrument. In the latter some sounds are exaggerated, while others are impaired, and there are not the distinctness and simplicity that are observable when we use the ear or the monaural instrument. It is an acoustic fact that sounds are better heard with two ears than with one, and virtually the double stethoscope enables us to place two ears on the chest at the same time. The modified instrument increases the intensity of sounds both by bringing the pectoral end into the closest possible contact with the chest, and by both the hollow air chamber and the rubber bulb acting as resonators. It also leaves both hands of the auscultator free. Alison's hydrophone may be used either by itself or placed between the end of the stethoscope and the chest, thereby increasing the contact and the conducting power when it is difficult to bring the inflexible end of the instrument into close apposition with the chest wall. Bowles' stethoscope is useful in listening to the posterior portions of the lungs in cases of pneumonia in which the patient cannot be turned over.

The value of the stethoscope for purposes of modesty, cleanliness, and convenience, and for examining the supraclavicular and axillary regions which cannot readily be reached by the ear, are obvious, and need only to be mentioned to be appreciated. *Donald M. Cammann.*

STILLINGIA.—U. S. P., *Queen's Root.* The dried root of *Stillingia sylvatica* L. (fam. *Euphorbiaceæ*). This is a perennial plant, with a large, tough, spongy root, and erect herbaceous or slightly woody stem, a foot or so in height, growing abundantly in the Southern States, where it has been used for about half a century.

The drug usually occurs in short transverse sections of very long, tapering, slenderly fusiform roots, about 2.5 cm. (1 in.) or less in thickness, very light, tough, and spongy; externally of a deep or occasionally a light reddish-brown, finely, shortly, and crookedly longitudinally wrinkled and incompletely annulate, especially the thicker portions, with constrictions which frequently become slight fissures; ends of the sections pinkish, very fuzzy with innumerable partly detached fine bast fibres, the bark very thick, containing scattered fine resin cells and laticiferous ducts; the wood radiate, fibrous, and porous; odor slight, peculiar; taste pungent, bitter, and acrid.

The activity of stillingia depends upon three or four per cent. of a nauseous volatile oil, a large amount of soft resin, and a fixed oil, the composition of which has not been studied, but which apparently holds an acrid substance in solution. There are considerable tannin, starch, and other unimportant constituents.

Stillingia is an emetico-cathartic, like many other plants of its family, and is said to be "alterative." Upon this property depend its principal uses, which are very similar to those of sarsaparilla, in syphilis, rheumatism, gout, etc. That its use is mildly beneficial cannot be doubted. Belonging to the same family with the castor and croton-oil plants (see *Euphorbiaceæ*), it rather actively promotes the excretions, from which result its amelioration of the above-named diseases evidently proceeds. Dose 1 or 2 gm. (gr. xv. to xxx.) two or three times a day. A fluid extract is official (*Extractum Stillingiæ Fluidum*, U. S. P.), dose 1–2 c.c. (♏ xv.–xxx.).

Henry H. Rusby.

STOMACH.—The stomach exhibits the usual four layers found in the alimentary tract, called, from within outward, the tunica mucosa, the tela submucosa, the tunica muscularis, and the tunica serosa.

The tunica mucosa is the glandular lining membrane of the stomach. In the fresh condition it is of fleshy consistence and of a pinkish color. The color of the fresh mucous membrane depends on three factors—the amount and venosity of the blood contained in its vessels, the physiological condition, and the character of the glands. In the dog, in the resting condition, the mucous membrane of the greater curvature of the stomach presents a grayish-pink appearance and is relatively opaque. After digestion has been going on for some hours, the grayishness and opacity disappear and the mucous membrane presents a rose-pink color.

If the veins are engorged, the grayish-pink tint is deepened to a chocolate-pink, which rapidly brightens on exposure to the air. The mucous membrane of the pyloric portion of the stomach is always more transparent, paler in color, and firmer in consistence than that of the fundus and corpus ventriculi.

The point of contact of the œsophageal and gastric mucous membranes at the cardia forms a somewhat zigzag line, the œsophageal epithelium extending in the form of irregular conical projections into the stomach (Schaffer) in such a manner that frequently in longitudinal sections engaging the termination of the œsophagus and the beginning of the stomach, portions of the epithelium of the former may appear as isolated patches surrounded by gastric epithelium. This irregularity of the gastro-œsophageal junction is an indication of that tendency of the œsophageal epithelium to invade the stomach and displace the glands, which in some of the lower primates, Inuus, Semnopithecus, etc., has resulted in the formation of a distinct chamber of the stomach, lined by stratified epithelium. At the summit of the musculus sphincter pylori the gastric mucous membrane is continuous with the tunica mucosa duodeni.

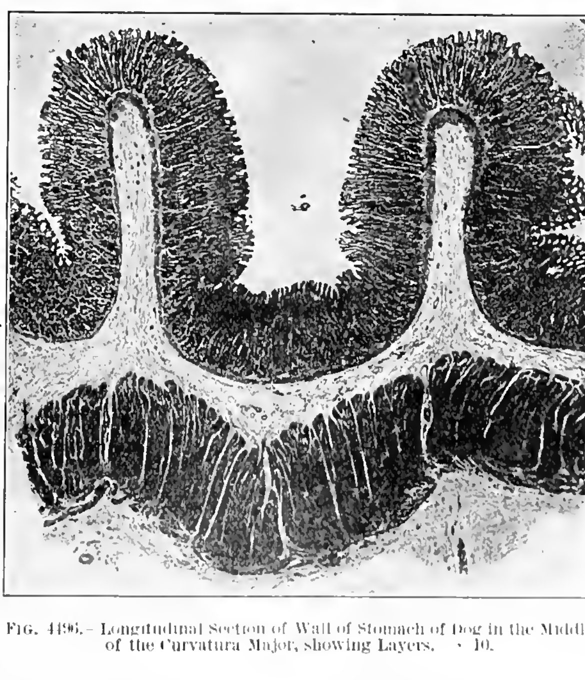

FIG. 4496.—Longitudinal Section of Wall of Stomach of Dog in the Middle of the Curvatura Major, showing Layers. × 10.

In the contracted stomach the tunica mucosa is thrown up into a series of coarse folds, the plicæ mucosæ, mainly longitudinal in direction, but with transverse and oblique connecting folds. These plicæ mucosæ involve the whole thickness of the tunica mucosa and the superficial layer of the tela submucosa. When the stomach is distended to its utmost the folds disappear. A permanent fold at the pyloric end of the stomach, caused by the projection into the cavity of the musculus sphincter pylori, forms the valvula pylori.

The whole surface of the mucous membrane in man is indistinctly marked off by irregular sulci, of varying depths, into small fields a few millimetres in width, the areæ gastricæ, giving the tunica mucosa the so-called mammillated appearance.

If the surface of the mucous membrane be examined with a lens, the close-set depressions, foveolæ gastricæ, into which the gastric glands open, may be seen. These openings are separated from one another by delicate partitions which are in the pyloric region often continued into pointed villus-like processes, projecting into the cavity of the stomach as the plicæ villosæ. Cases have been reported in which the whole inner surface of the stomach was beset with these villus-like processes. The number of foveolæ opening upon the surface of the gastric mucous membrane has been estimated by Toldt to be eighty-seven per millimetre. The total extent of the mucous membrane measured in the same individual by means of the planimeter was 76,300 sq.mm., giving 6,638,100 as the total number of foveolæ in the stomach. It seems probable, however, that the number of foveolæ is subject to considerable variation in different individuals. In a number of pathological cases reported by Einhorn, the number varied from twenty to one hundred and sixty per square millimetre.

The whole of the surface of the mucous membrane and the walls of the foveolæ gastricæ are covered with a simple cylindrical epithelium, mucigenous in function, uniform in type throughout the stomach, but differing somewhat in structural details in the different regions. The cells of this epithelium are somewhat conical in shape, but vary with the shape of the surface upon which they rest, the conical shape being more pronounced on convex surfaces. The pointed apex of the cell rests against the reticular tissue of the lamina propria mucosæ; the broad, slightly convex base of the cell is directed toward the free surface of the tunica mucosa. The adjacent surfaces of the epithelial cells are separated from one another by minute spaces, across which the cells are connected by protoplasmic intercellular bridges. The intercellular spaces are closed internally by lines of cement (*Schlussleisten* of Kohn) which connect the adjacent free edges of the cells. This cement substance is not entirely confined to the intercellular location, but, as shown by Carlier in the newt and by Bensley in man, extends over the free surface of the cell in delicate radiating lines which may easily be mistaken by an inexperienced observer for traces of a striated cuticula. The distal portion of each epithelial cell forms a cup-like cavity, the theca, which contains the specific secretion of the cell; in this case mucin or its antecedent substance. The contents of the theca are in the form of small droplets, which appear in sections of properly fixed material, stained in an alcoholic solution without exposure to water, as fine granules. If the mucin has been allowed to absorb water and go into solution, it precipitates in the form of the coarse spongy network which is usually seen in the theca of these cells. The distal portion of the theca contains very little cytoplasm, but in the proximal portion the granules are separated into groups by threads of cytoplasm which form a coarse network. The conical attached end of the cell is occupied by a delicately reticular cytoplasm containing an oval nucleus. This cyto-

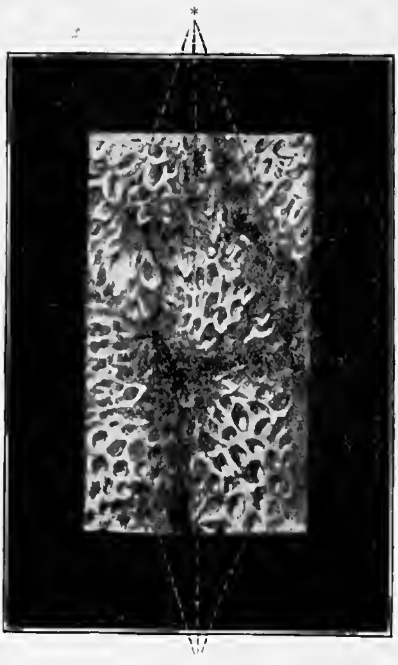

FIG. 4498.—Tunica Mucosa of the Pyloric Region, showing at * the Openings of the Gastric Foveolæ, the Villous Folds, and the Small Gastric Areas. × 16 (After W. Spalteholz, "Handatlas der Anatomie des Menschen.")

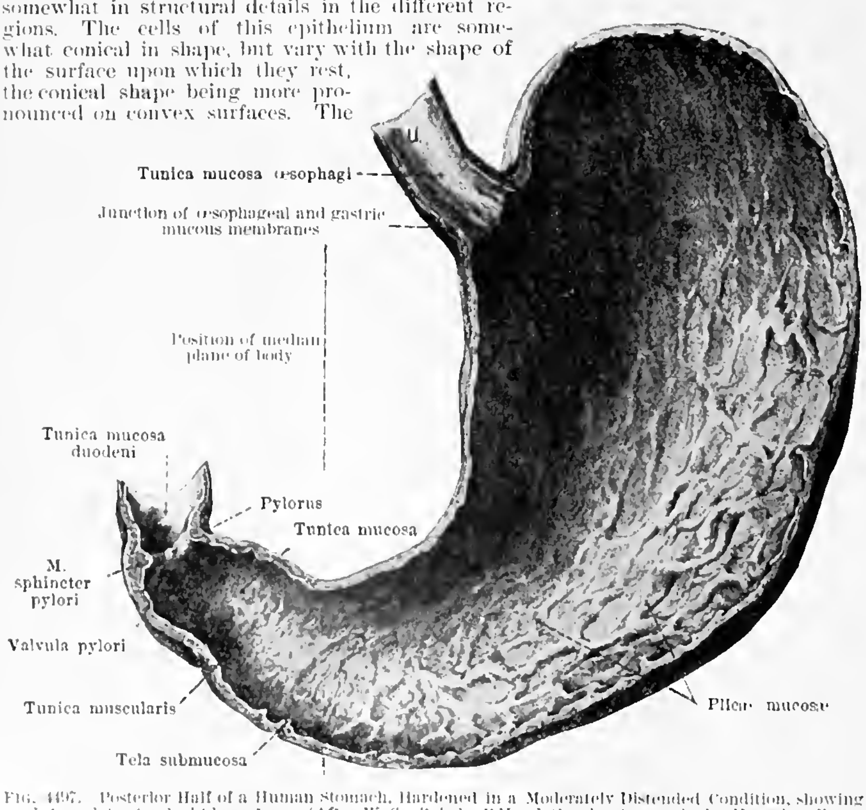

FIG. 4497. Posterior Half of a Human Stomach, Hardened in a Moderately Distended Condition, showing Internal Anatomical Characters. (After W. Spalteholz, "Handatlas der Anatomie des Menschen.")

plasm is continuous with the cytoplasmic network of the proximal portion of the theca, and frequently contains, in sublimate-fixed preparations around the base of the theca, numerous minute granules stainable in eosin or acid fuchsin.

Between the nucleus and the theca the cytoplasm stains less deeply than that in the base of the cell, owing to the presence of the structures which have been interpreted by Holmgren as similar to the canal-like structures observed by him in the hepatic cells, to which he has applied the name trophospongium.

The so-called replacing cells (*Ersatzzellen* of Ebstein) do not exist in the epithelium of the stomach, the structures which have been described under this name being, as suggested by Stöhr, in all probability, lymphocytes which have invaded the epithelial layer.

The epithelium of the foveolæ gastricæ is, as has been indicated, similar to that of the free surfaces, but on going down the foveolæ, certain changes of a transitional character make their appearance as the bottom of the depression is approached. Near the mouth of the foveola the cells are slightly imbricated at their attached ends and have a larger theca than those of the free surface. Deeper in the foveola the cells become shorter and more cubical in shape, the nucleus larger, more rounded, and richer in chromatin; the theca tends to become smaller in extent and divided into two more or less distinct masses, a proximal mass near the nucleus and a distal mass near the cavity. These smaller cells of the bottom of the crypt exhibit great activity in division, as is indicated by the presence of numerous mitoses. The cells of the surface, on the other hand, rarely divide. On this fact Bizzozero has based his theory of the mode of regeneration of the surface epithelium, according to which the cells of the bottoms of the crypts are endowed with the property of dividing and producing new cells, which by a gradual process of migrating or displacement finally reach the surface and replace the cells, which for various reasons are being constantly lost there.

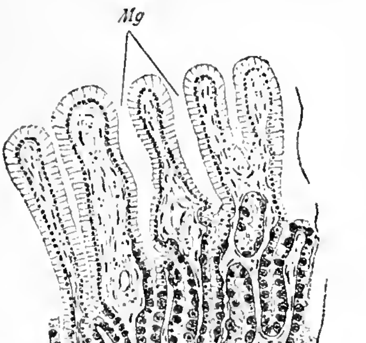

FIG. 4499.—Vertical Section through the Mucous Membrane of the Fundus Gland Region of the Stomach. × 85. *Mg*, Foveolæ gastricæ; *h*, neck of gland; *k*, body of gland; *m*, lamina muscularis mucosæ. (After V. von Ebner, in von Kölliker's "Handbuch der Gewebelehre des Menschen.")

A point of some interest is the occasional occurrence in the human stomach, on the surface of the tunica mucosa, or in the foveolæ, of epithelium of the intestinal type, that is to say, composed of cells with a distinct striated cuticula alternating with goblet cells (Schaffer, Boeckelman, Hári). There is still some doubt as to whether these patches of intestinal epithelium occur normally in the human stomach. They appear to occur most frequently in the pyloric region, but have been observed by Schaffer at the very margin of the œsophagus in the foveolæ of the cardiac glands.

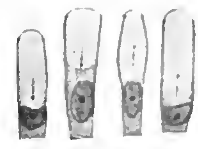

FIG. 1500.—Types of Epithelial Cells from the Gastric Mucosa of Man. (After K. W. Zimmermann. *Arch. f. mikr. Anat.*, Bonn, Bd. lii.)

The great thickness of the gastric mucous membrane is caused by the closely aggregated tubular or tubulo-acinous glands. These are of three kinds, occupying three definite regions of the mucous membrane. The *cardiac glands* (glandulæ cardiacæ) form in man a small area around the cardiac orifice of the stomach, which varies in width in different individuals and in different parts of the circumference of the cardia in the same individual, the extremes, so far recorded, being 0.5 cm. in one of Kupffer's cases, 4.3 cm. in a case described by the writer. The tunica mucosa of the fundus ventriculi, of the curvaturæ major et minor, and of the parietes anterior et posterior is occupied by the *fundus glands* (glandulæ gastricæ propriæ), that of the antrum pyloricum and the adjacent portions of the stomach, by the *pyloric glands* (glandulæ pyloricæ). The cardiac and pyloric glands are, for the most part, mucous glands of simple structure, the acid and pepsin of the gastric juice being in large measure produced by the complex fundus glands.

At the lines of junction of the various glandular zones a gradual transition from one type of gland to the next may be observed, forming thus between the cardiac and fundus zones on the one hand, and between the fundus and pyloric zones on the other hand, intermediary zones of small extent.

The tunica mucosa in the region occupied by the fundus glands differs in thickness according to the location. In man, according to von Kölliker, the thickness of the tunica mucosa is 0.37 mm. to 0.56 mm. at the cardia, 1 mm. in the middle of the greater curvature. Zimmermann gives the thickness of the mucous membrane as 1.2 mm. in a piece of mucous membrane from the fundus gland zone. In material examined by the writer, the thickness of the mucous membrane, including the lamina muscularis mucosæ, was 0.64 mm. at the beginning of the fundus glands, 0.82 mm. in the middle of the fundus ventriculi, 1.2 mm. to 1.3 mm. in the middle of the curvatura major.

The fundus glands (glandulæ gastricæ propriæ), physiologically the most important, are slightly wavy, branched tubules, placed vertically in the tunica mucosa, and so closely aggregated throughout the whole of the zone that the interglandular tissue of the lamina propria mucosæ is reduced to a minimum. Each gland is connected with a foveola gastrica by a short collecting duct (*inneres Schaltstück* of Rollett), lined by epithelium of the same type as that of the deep ends of the foveolæ.

The gland may be divided into two portions, which differ from one another in size and in the character and arrangement of their respective epithelial elements. The more superficial, narrower portion of the gland is called the neck of the gland; the deeper, wider portion, the body of the gland.

The relative lengths of the foveolæ and different sections of the glands is given by Zimmermann as follows:

Thickness of the tunica mucosa	1.200 mm.
Depth of the foveolæ gastricæ	0.256 to .325 "
Collecting duct (*Drüsenhals* of Zimmermann)	.046 to .078 "
Neck of gland (*Schaltstück* of Zimmermann)	.265 to .312 "
Body of gland	.465 to .578 "

The measurements obtained by the writer correspond very closely with those of Zimmermann as regards the length of the body of the gland, but show relatively longer foveolæ and shorter necks. They are as follows, taken from glands of the middle of the greater curvature of the stomach:

Thickness of tunica mucosa	1.200 to 1.320 mm
Combined length of foveolæ and collecting duct	.358 to .539 "
Neck of gland	.147 to .220 "
Body of gland	.414 to .526 "

The differences between these two sets of measurements possibly indicate that there is considerable individual variation in the relative lengths of the foveolæ and the necks of the glands.

The fact that the fundus glands of the stomach are composed of several kinds of cells was discovered in 1850 by von Kölliker, who described them as composed of very large mononucleated cells, located immediately beneath the membrana propria, and of smaller rounded cells which formed a complete tube around the very narrow lumen. This discovery, however, attracted little attention from histologists, and even von Kölliker himself failed to mention it in the subsequent editions of his text-book. The two kinds of cells were subsequently rediscovered in 1870, independently of one another, by Heidenhain and Rollett. The former called the chief cells and parietal cells respectively *Hauptzellen* and *Belegzellen*. By Rollett the chief cells were called "*adelomorphe Zellen*," the parietal cells, "*delomorphe Zellen*."

The descriptions of Heidenhain and Rollett differed in some important respects. The former described the neck of the gland as being composed of both chief and parietal cells, and mentioned the occasional occurrence of parietal cells under the cylindrical epithelium. Rollett denied both the existence of chief cells in the neck of the gland, which he supposed to be wholly composed of parietal

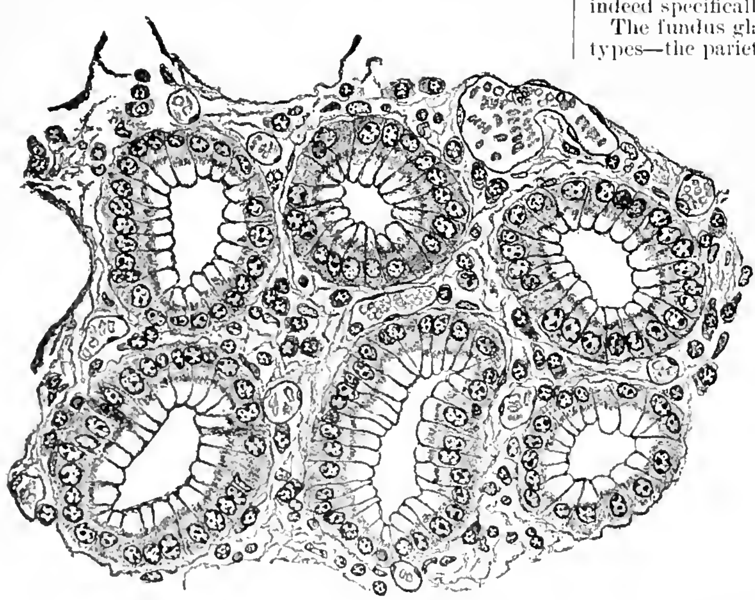

FIG. 4501.—Section Cut Parallel to the Surface of the Mucous Membrane of the Greater Curvature of the Human Stomach, Across Six Foveolæ Gastricæ, showing the Type of the Epithelium and the Tissue of the Lamina Propria Mucosæ. Note the large number of plasma cells in the latter. × 394.

cells, and the occurrence of the latter in the foveolæ. The researches of subsequent investigators, in particular those of Stöhr, have amply sustained Heidenhain in both these respects. In 1892 Bizzozero called attention to the fact that the chief cells in the neck of the gland differed somewhat from those in the body of the gland. The question as to the nature of these cells has since been investigated by Oppel, Bensley, Zimmermann, Cade, and

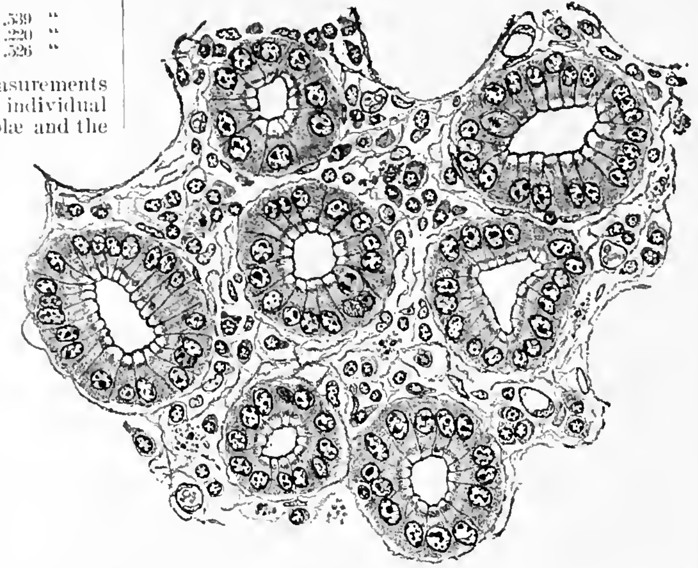

FIG. 4502.—Section Across the Foveolæ Near their Outer Ends. Note the smaller size of the foveolæ as compared with Fig. 4501; the smaller mucigenous border (theca) of the epithelial cells; the mitoses; and the larger amount of interglandular tissue. × 394.

others, and it has been shown that the transition which Bizzozero supposed to exist between the chief cells of the neck of the gland and those of the body of the gland does not occur, and that the two kinds of chief cells are indeed specifically different.

The fundus gland is composed of cells of three distinct types—the parietal cells, large, ovoidal elements projecting on the outside; the mucous cells of the neck of the gland (*Halshauptzellen* of Oppel); and the pepsin-forming chief cells of the body of the gland (*Grundhauptzellen* of Oppel).

In the body of the gland, the large, wedge-shaped or cuboidal chief cells form an almost continuous lining for the narrow lumen, the large ovoidal parietal cells being displaced to the periphery of the gland away from the lumen, with which they are only connected by narrow ductlets which pass between the adjacent surfaces of the chief cells.

In sections of fresh mucous membrane, mounted in an indifferent fluid (aqueous humor or blood serum), the portions of the chief cells of the body of the gland which border the lumen are seen to be occupied by closely packed minute refractive granules. These granules have been shown by Langley in a number of mammals and lower vertebrates to diminish in number during secretory activity and to accumulate during rest. Langley has also shown that the amount of pepsin which may be extracted from the mucous membrane is proportional to the extent of this superficial granule-filled zone of the chief cells. The granules are therefore composed of the antecedent substance of the enzyme, and are called zymogen granules. The zymogen granules in the gastric mucosa of man are exceedingly difficult to preserve, and for this reason are usually not visible in stained sections. In material fixed in alcohol or in aqueous solutions of mercuric chloride they have, as a rule, completely disappeared. They may be retained by fixation of the tissue in alcoholic solutions of mercuric chloride or in solutions containing four per cent. of formaldehyde.

In sections of tissue fixed by mercuric chloride in alcohol and stained in hæmatoxylin, or, better, in toluidine blue, the chief cell of the body of the gland exhibits two well-defined zones—a deeply stained proximal zone containing the nucleus, and a pale distal zone bordering the lumen. The relative sizes of these two zones depend on the physiological condition of the cell, the clear zone being larger in a resting cell, smaller in a cell which has been actively secreting for several hours. The cytoplasm of the basal zone stains intensely in nuclear dyes such as hæmatoxylin, toluidine-blue, thionin, methylene-blue, etc., and exhibits an indistinct radial striation, which has been interpreted by some observers as due to the presence in the cytoplasm of groups of parallel filaments (the basal filaments of Solger). The intense staining of the basal zone has been shown by the writer to be due to the presence in it of substances chemically similar to the chromatins of the nucleus. This may be shown by the employment of Macallum's microchemical tests for iron and phosphorus, both of which give distinct positive reactions, quite as intense as those given by the nuclear chromatin. There is a reciprocal relation between the amount of these substances and the number of zymogen granules bordering the lumen of the gland, the latter being formed apparently in part at the expense of the former. These substances, on the presence of which depends the deep staining character of the basal zone, may therefore be termed prozymogens. The amount of prozymogen and of zymogen present in any cell depends on the phase of physiological activity in which it happens to be, and on the specific secretory equilibrium of the cell. Macallum has shown in the pancreatic cell, and Carlier in the cells of the gastric glands of Triton, that the increase of prozymogen in the basal cytoplasm is accompanied by an exhaustion of the nuclear chromatin, indicating an actual participation of the latter in the secretory metabolism of the cell.

The transparent distal zone of the chief cells of the body of the gland, that is, the zone that is next the lumen of the gland, exhibits a finely reticular structure, the meshes of the network being of wonderful regularity and corresponding in size to the zymogen granules observable in the living cell. This reticular appearance has been interpreted by Théohari and others as due to the presence of a true cytoplasmic reticulum or spongioplasm. The more probable explanation is that the cytoplasm of the portion of the cell nearest the lumen contains innumerable small granules of zymogen, each granule enclosed in a space separated from the neighboring spaces by the continuous cytoplasm. In sections stained in alum hæmatoxylin and eosin or in toluidine-blue, the granules remain unstained and the spaces they occupy appear as tiny vacuoles, so closely aggregated that the portion of the cell in which they occur appears reticulated. The correspondence between the granules and the meshes of the cytoplasmic network may be demonstrated by staining sections of material fixed fresh in formalin or in alcoholic solution of mercuric chloride, in iron alum hæmatoxylin, or in neutral gentian. By these methods the zymogen granules are intensely stained, and it may be readily seen that each granule is enclosed in a mesh of the network.

The nucleus of the chief cell of the body of the gland is located at the junction of the two zones, is spherical in outline, and possesses one or two oxyphile nucleoli and a well-defined chromatin network.

It has been shown by the writer and confirmed by Cade that the chief cells of the neck of the gland differ in several important points from those of the body of the gland. These cells lack both prozymogens (there is no indication of basal filaments in them) and zymogen granules. In the living gland the contrast between the two portions of the gland is very striking, owing to the fact that the zymogen granules are entirely confined to the body of the gland.

The neck chief cells resemble very closely the mucous cells from salivary glands. For the most part they appear triangular when seen in longitudinal sections of the gland, the broad base of the triangle directed toward the lumen, the narrow apex toward the outside, where the cells are crowded by the presence of the parietal cells. The nucleus is located in the proximal attached end of the cell and is spherical, oval, or crescentic in outline, according to the degree of loading of the cell with secretion. The contents of the cell appear in hæmatoxylin-eosin sections clear and transparent, and exhibit a reticular structure, the large meshes of which are separated by delicate protoplasmic trabeculæ. The meshes or clear spaces in such preparations are the cavities of the cell in which the secretion is stored. Usually there is in these cells a condensation of the cytoplasm in the

FIG. 4503.—Section Across Six Fundus Glands from the Greater Curvature of the Human Stomach, Near the Outer Ends. In the chief cells may be seen the two characteristic zones: the outer zone containing basal filaments of prozymogen; the inner zone a fine network enclosing the spaces in which the zymogen granules are lodged. × 500.

middle of the cell in the form of a transverse band, incompletely subdividing the secretion into a proximal and a distal mass. The nature of the secretion contained in these cells may be determined by staining in a modified form of P. Mayer's muchæmatein solution of the following composition: Hæmatein, 1 gm.; aluminum chloride, 0.5 gm.; seventy-per-cent. alcohol, 100 c.c. The sections fastened to the slide are stained in this solution under the microscope until the mucin of the surface epithelial cells is a deep blue; the stain is then washed off with ninety-five-per-cent. alcohol, and the sections are dehydrated, cleared, and mounted in xylol balsam. In such preparations the contents of the secretion spaces of the neck chief cells, as well as the mucin of the surface cells, are stained intensely blue. A similar result is obtained by staining sections with Mayer's mucicarmine, freshly prepared and undiluted, the contents of the neck chief cells and of the theca of the epithelial cells of the foveolæ gastricæ staining in this solution intensely red. Thus the impression gained by a study of the structure of these cells that they secrete mucus is confirmed by the staining reactions.

At the junction of the neck and body of the gland for a very short distance the mucous cells and zymogenic cells are mixed with one another, affording at this place a good opportunity to compare their respective cytological characters. In a very few of the glands of the fundus the mucous cells extend right to the bottom of the gland, replacing entirely in this case the ordinary chief cells of the body of the glands. Such mucous glands contain fewer parietal cells and a larger lumen than the ordinary fundus glands. The mucous chief cells of the neck of the fundus gland of man and mammals are the homologues of the large clear cells found in the necks of the gastric glands of reptiles and anurous Batrachians, with which they correspond in position, structure, and staining characters.

The parietal cells occur in all parts of the gland, although they may be found in greatest numbers in the necks of the gland, alternating in this situation with groups of the mucous neck cells. In the body of the gland they are fewer in number, and in the foveolæ only an occasional parietal cell may be seen.

The parietal cells are of ovoidal shape with centrally placed nuclei. In the neck of the gland they have a broad surface of contact with the lumen, but in the body of the gland they are crowded to the outside of the gland, and are connected with the lumen only by narrow ductlets which pass between the adjacent surfaces of the chief cells. In each parietal cell according to Zimmermann, three zones of structure can be made out, a central mass of coarsely granular structure, containing the spherical nucleus or nuclei, for the latter are often multiple, a peripheral zone of similar structure, and an intermediate zone of finely granular structure. The differences between these various zones are best brought to view by staining sections according to Heidenhain's iron hæmatoxylin method, in which the coarse granules of the middle and outer zones stain deeply. The intermediate zone forms the free surface of the cell on the lumen or on the minute ductlets above described.

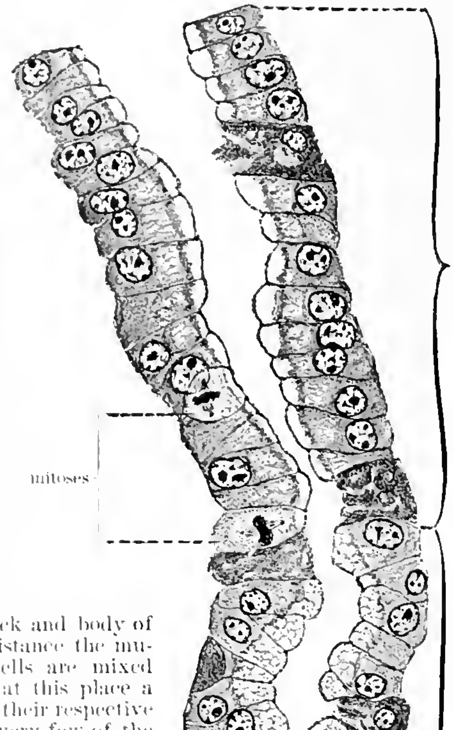

FIG. 4504. Longitudinal Section of Part of a Foveola Gastrica, of the Neck, and of Part of the Body of a Fundus Gland of the Stomach of Man. × 580.

For a long time it was thought that the parietal cells in the body of the gland were completely shut off from the lumen by a layer of chief cells. Stöhr was the first to point out that the parietal cells also came into contact with the lumen. According to him this connection was effected by the parietal cell possessing a pointed projection which penetrated between the adjacent surfaces of the chief cells and thus reached the lumen of the gland. It was not, however, until the introduction of the rapid Golgi method for the impregnation of tissue spaces that the real nature of the ductules of these cells was determined. By this means Erik Müller was able to show not only that a minute canal ran from the lumen of the gland to the parietal cell, but that the latter possessed an intricate system of branching and anastomosing secretion canaliculi. These intracellular canaliculi have since been observed by Müller, Zimmermann, and others in ordinary stained preparations, especially in sections stained by the ferric alum hæmatoxylin method of M. Heidenhain, in which the intracellular and intercellular secretion canaliculi may be readily seen. In Golgi preparations of the gastric glands the fine ductule which connects the parietal cell with the lumen of the gland is seen to divide, on arriving at the cell, into a group of fine branches, most of which penetrate the substance of the cell, in the intermediate zone of which they ramify (intracellular canaliculi); others penetrate a short distance between the parietal cell and the adjacent chief cells (intercellular canaliculi). The true intercellular character of the latter may be determined, as Zimmermann has shown, by the presence of the intercellular cement lines. The ductules of the intracellular canaliculi frequently contain transparent globules of coagulated secretion, which may also be observed in the lumen of the gland as far as its opening into the foveola gastrica.

The theory of Heidenhain that the parietal cells are the sole source of the hydrochloric acid of the gastric juice rests at present on a very insecure foundation. The argument commonly employed, that the parietal cells are absent from the pyloric glands which produce an alkaline secretion, would be equally true of the chief cells of the body of the fundus glands. Moreover, the difference in acidity of the mucous membrane of the fundus and greater curvature of the stomach of the rabbit, which, according to Langley, corresponds to differences in the number of parietal cells present, could be equally well explained by the obvious differences in secretory equilibrium of the chief cells from these two sources.

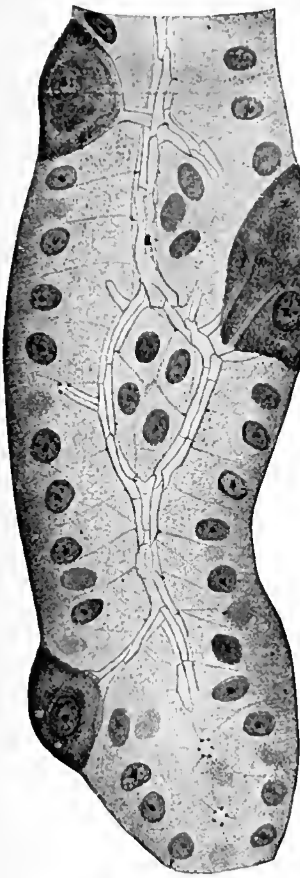

FIG. 4505.—Lower End of Fundus Gland, Chief and Parietal Cells. In the latter the intracellular ducts may be seen. (After K. W. Zimmermann, *Arch. f. mikr. Anat.*, Bonn, Bd. lii.)

The mucous membrane of the greater part of the pars pylorica is thinner than that of the greater curvature, although thicker than that of the fundus and cardia. The thickness in material examined by the writer was 0.832–0.955 mm. Near the sphincter pylori, however, it again increases in thickness to 1.3 mm., or in places as much as 1.8 mm.

The glands of the pyloric region are much less closely set than in the fundus region, and are separated from one another by a larger amount of tissue belonging to the lamina propria mucosæ.

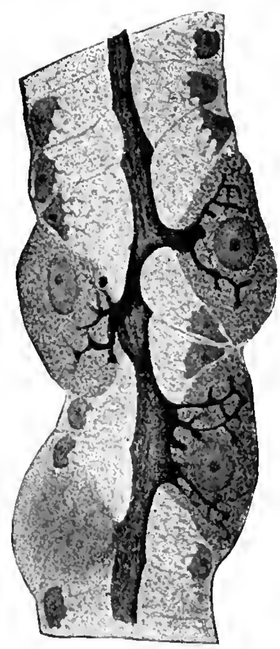

FIG. 4506.—Fundus Gland of Cat. Golgi preparation, fixed in ammonium sulphide and stained with hæmatoxylin and eosin; showing intracellular ducts of the parietal cells. (After K. W. Zimmermann, *Arch. f. mikr. Anat.*, Bonn, Bd. lii.)

The foveolæ into which the pyloric glands open are much narrower in man than in most mammals. They rapidly diminish in diameter, to become narrow tubes, which branch as they descend in the mucous membrane, and at about the junction of the middle and outer thirds of the mucous membrane receive the pyloric glands. The long tubular branches of the foveolæ in the pyloric region may be compared to the short collecting ducts of the fundus glands. In view, however, of the fact that they are lined throughout by epithelium similar in character to that of the foveolæ, it seems to me better to consider them as part of the latter.

Into the bottoms of these foveolar branches open the pyloric glands. These are composed of a varying number of branching wavy tubules, into which open short, pear-shaped acini. Both tubules and acini are lined by the characteristic pyloric gland cells. The thickness of the portions of the mucous membrane occupying the foveolæ and glands respectively, I have determined as follows:

Length of foveolæ and branches	0.441–0.476 mm.
Width of portion of tunica mucosa occupied by the glands proper	.283–.301 "

In the thicker distal portion of the pyloric mucous membrane they are as follows:

Length of foveolæ and branches..................	0.735 mm.
Width of mucosa containing glands proper........	.301 "

The narrow tubular branches of the foveolæ are lined by cells of the type of those found at the bottoms of the gastric foveolæ and in the short tubules which are intercalated between these and the neck of the glands in the fundus region. They are cylindrical cells, containing an oval nucleus and a considerable amount of cytoplasm. At the end of the cell which borders on the lumen a small theca is seen containing mucus, stainable in mucihæmatein according to the method already described.

The terminal branches of the pyloric gland are made up of large, cubical cells surrounding an obvious lumen. These cells are usually found filled with secretion which occupies the meshes of a coarse network of cytoplasm. The nucleus is situated at the base of the cell and is spherical, flattened, or crescentic in outline, according to the amount of the secretion contained in the cell.

The theory of Heidenhain that the cells of the pyloric glands are pepsin-forming elements similar in character to the chief cells of the body of the fundus gland, has been shown to be incorrect.

As has been pointed out, the chief cells contain two characteristic substances which are phases in the formation of their secretion, namely, prozymogen, a deeply staining substance found in the base of the cell; and zymo-

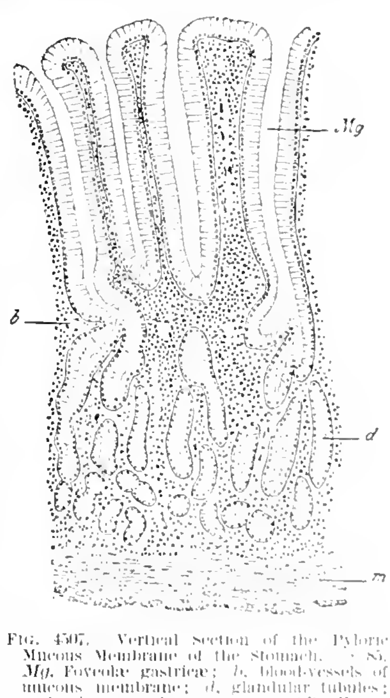

FIG. 4507.—Vertical Section of the Pyloric Mucous Membrane of the Stomach. × 85. *Mg*, Foveolæ gastricæ; *b*, blood-vessels of mucous membrane; *d*, glandular tubules; *m*, lamina muscularis mucosæ. (After V. von Ebner in von Kölliker's "Handbuch der Gewebelehre.")

gen, found in the form of coarse granules along its free surface. Neither of these substances occurs in the pyloric gland cells. The absence of the granules explains the greater transparency of the pyloric mucous membrane. On the contrary, the meshes of the coarse network seen in the pyloric gland cells are filled with a substance which stains strongly in muchæmatein or mucicarmine, when employed according to the methods indicated above. These facts, together with the strong resemblance of the pyloric gland cells to mucous cells from other sources, and the gradual transition in character from the gland cells to the cells of the superficial epithelium, indicate that the bulk of the secretion of the pyloric glands is simply mucus. What other subsidiary substances are secreted along with the mucin is at present unknown.

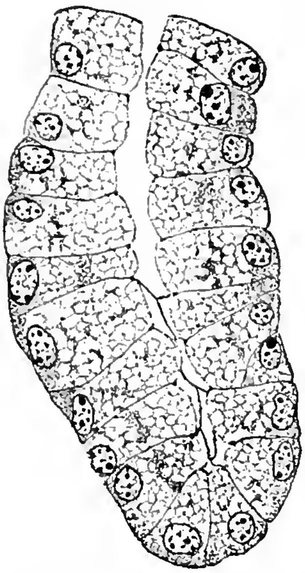

FIG. 4508.—Tubule of Pyloric Gland of Man. (Highly magnified.) Note the thin basal layer of cytoplasm; the reticular cell body containing secretion; the subdivision of the latter in some cells into proximal and distal masses.

Morphologically and physiologically the cells of the pyloric glands are regarded by the writer as the equivalents of the mucous chief cells found in the necks of the fundus glands. The same relation thus obtains between the pyloric glands and the fundus glands of mammals as between the corresponding structures in Reptilia and Anura.

The cardiac glands occupy a zone varying in width from 0.5 cm. to 4.3 cm. around the cardiac orifice of the stomach. The glands of the proximal portion of this area are much more richly branched than either the fundus glands or the pyloric glands. They are composed largely of cells similar in character to the pyloric gland cells and the mucous chief cells of the fundus glands, and like them contain a secretion which stains in mucihæmatein and mucicarmine. Some tubules are, however, formed of cells similar in type to the chief cells of the body of the fundus gland, inasmuch as they contain both prozymogen and granules of zymogen. A few parietal cells may also be present in the cardiac glands.

Toward the distal part of the zone the glands become less branched, and chief cells make their appearance regularly at their outer ends, a transition being thus gradually accomplished from the cardiac glands to the fundus glands.

The framework of the tunica mucosa is composed of reticulum, which forms a delicate network supporting and separating the glands and containing the blood-vessels, nerves, etc., of the membrane. The delicate fibrils of which this tissue is composed are condensed around the surfaces of the glands to form basement membranes for them. In the dog, according to Mall, the reticulum is especially condensed at two levels in the mucosa, one just above the lamina muscularis mucosæ, corresponding to a rudimentary stratum fibrosum (stratum compactum of Oppel); the other at the level of the necks of the glands. In man the glands reach almost to the muscularis mucosæ, so that here also the stratum fibrosum of Mall is rudimentary.

Here and there in the tunica mucosa branching bands of smooth muscle extend between the glands from the muscularis mucosæ in the direction of the free surface. These also receive a delicate investment of reticular fibrils, containing a network of fine elastic fibres.

In the meshes of the reticular framework many wandering cells occur. In the superficial portions of the mucous membrane Unna's plasma cells are especially abundant (Figs. 4501 and 4502). A few polymorphonuclear neutrophile and eosinophile leucocytes, and lymphocytes, are present, and in sections stained in polychrome methylene-blue numerous mast cells may be seen among the glands.

Solitary lymph nodules (noduli lymphatici solitarii) occur in varying numbers in the mucous membrane of the stomach. They are particularly abundant in the cardiac and pyloric regions, where they occupy the deeper layers of the mucous membrane. Occasionally they may be found in the superficial tela submucosa, in which case they are often continuous through an opening in the lamina muscularis mucosæ with the reticular tissue of the tunica mucosa.

The deepest layer of the tunica mucosa is formed by the lamina muscularis mucosæ, a double layer of unstriated muscle fibres, 50–100 μ in thickness. It consists, according to Klein, of an inner circular and an outer longitudinal layer of fibres, which intercross and pass into one another. According to Böhm and von Davidoff it is composed of three layers. Between the constituent fibres of this layer may be seen a delicate network of reticulum and a rich network of elastic fibres. The fibres of the latter, for the most part, run in a direction parallel to the muscle fibres. From both layers of the lamina come off the groups of muscle fibres referred to above, ascending in the tunica mucosa among the glands.

The tela submucosa is a loose layer of collagenic fibrous tissue, connecting the tunica mucosa with the tunica

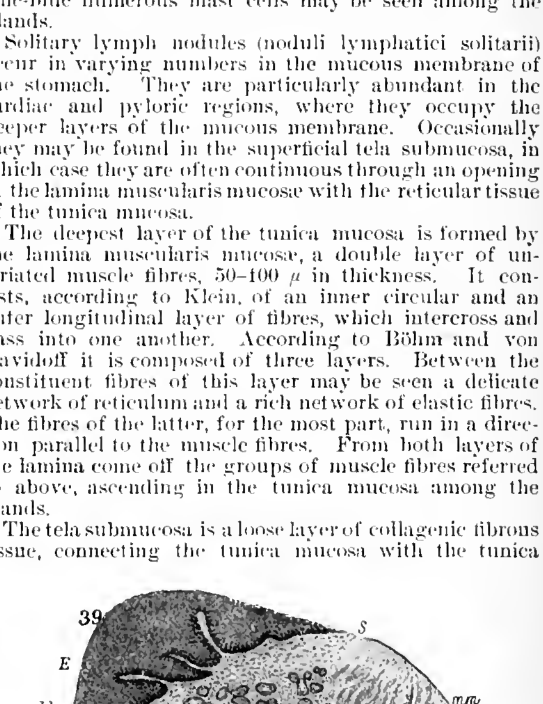

FIG. 4509.—Section through the Junction of Œsophagus and Stomach of Man, showing Cardiac Glands. × 121. *Oe*, Œsophagus; *m*, stomach; *cd*, cardiac glands; *wd*, dilated ducts of cardiac glands. (After J. Schaffer, *Sitzungsb. d. k. Akad. d. Wissensch.*, Wien, Bd. cvi., Abth. iii.)

muscularis, and containing the large blood-vessels and lymphatics and the nerves and ganglia forming the plexus of Meissner. This layer is poor in elastic fibres except in the neighborhood of the tunica muscularis, where the rich network of elastic fibres may be seen. Here and there, in the tela submucosa, are to be seen larger and smaller accumulations of adipose tissue.

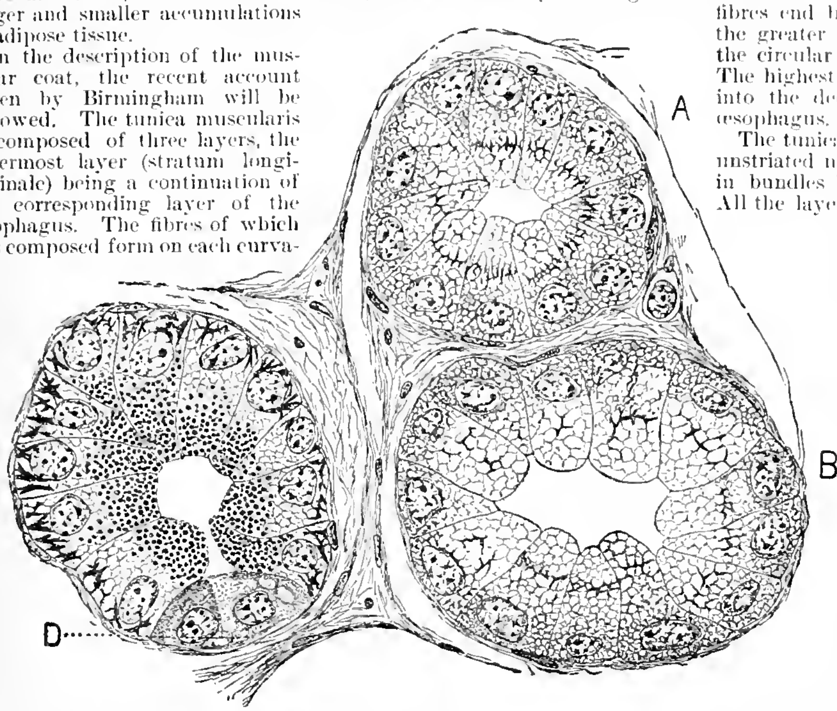

FIG. 4510.—Cross-section of Three Tubules of the Cardiac Glands of Man. × 1,000. A, Mucous tubule, showing cells in early stage of mucin formation; B, mucous tubule, showing cells in various stages of mucin formation up to complete loading; C, tubule composed of cells similar to the chief cells of the body of the fundus glands. These cells contain basal filaments (prozymogen) and zymogen granules; D, binucleate parietal cell with intracellular secretion channels. (After R. R. Bensley, '02.)

In the description of the muscular coat, the recent account given by Birmingham will be followed. The tunica muscularis is composed of three layers, the outermost layer (stratum longitudinale) being a continuation of the corresponding layer of the œsophagus. The fibres of which it is composed form on each curvature, but particularly on the curvatura minor, a well-marked layer of numerous distinct bundles. On the anterior and posterior surfaces the layer exists as a very thin sheet, the fibres being less distinctly longitudinal in places, particularly near the middle of the surfaces beneath the cardia, than in the neighborhood of the curvature (Fig. 4511). The middle layer (stratum circulare) is best developed at the pylorus, where it forms a thickened muscular ring, musculus sphincter pylori, surrounding this aperture. In the adjacent narrow portion of the stomach the fibres are also well developed, and the resulting rings are numerous and closely placed. As we pass on toward the left the layer becomes thinner and the rings correspondingly fewer, but they still form a distinct and well-defined continuous sheet, the fibres of which can be easily seen even through the peritoneum, forming very symmetrical rings, disposed at right angles to the long axis of the organ. This regular arrangement is continued as far as the region of the œsophagus, where it is interrupted. To the left of the cardia the layer is continued for some distance in the form of oblique fibres, which radiate from the right side of the œsophageal opening above, downward, and to the left on the two surfaces of the stomach. These fibres, becoming more and more oblique, are continued above into the superficial circular fibres of the lower end of the œsophagus. The internal layer is composed, like the middle layer, of circular and oblique fibres; but while the oblique fibres are but slightly developed in the middle layer, they form an important part of the internal layer. Beginning as a series of circles at the summit of the fundus, it extends in the form of a layer of rings, disposed at right angles to the axis of the stomach, as far as the cardia. Beyond this it is continued by a number of fibres—the well-known oblique muscular fibres of the stomach—which radiate from the left side of the œsophageal opening, downward, and to the right on both surfaces of the stomach, some of them reaching almost as far as the antrum pylori. These fibres end by turning abruptly toward the greater curvature and passing into the circular fibres of the middle layer. The highest of these oblique fibres pass into the deeper circular fibres of the œsophagus.

The tunica muscularis is composed of unstriated muscle fibres bound together in bundles by delicate reticular tissue. All the layers of this coat contain many elastic fibres forming networks, the meshes of which are elongated in the direction of the long axis of the fibres.

Between the strata is a thin layer of collagenic connective tissue, containing numerous blood-vessels and the nerves and ganglia of the plexus of Auerbach.

The peritoneal coat of the stomach (tunica serosa) consists of collagenic tissue, composed of crossing and intercrossing fasciculi and containing elastic fibres. The free surface is covered by a layer of flat, irregularly shaped nucleated endothelial cells, which give to the external surface its smooth, glistening appearance. Under the endothelium is a thin layer of connective tissue, containing in its deeper half a network of fine elastic fibres. The deeper layers of the tunica serosa, formed of connective tissue composed

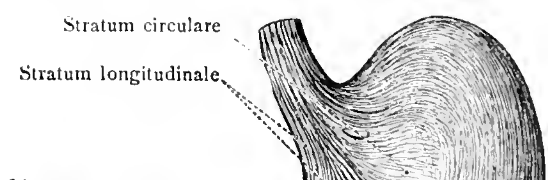

FIG. 4511.—The Superficial Layers of the Tunica Muscularis of the Stomach. Stratum longitudinale. (After C. Toldt, "Anatomischer Atlas," Zweite Auflage.)

of loosely interlaced fasciculi of collagenic fibrils and a few elastic fibres, contain the blood-vessels and nerve bundles.

The blood-vessels of the stomach are derived from all three branches of the arteria cœliaca, which form arterial arches along the curvaturæ minor et major, from which the smaller branches to the organ are derived. That

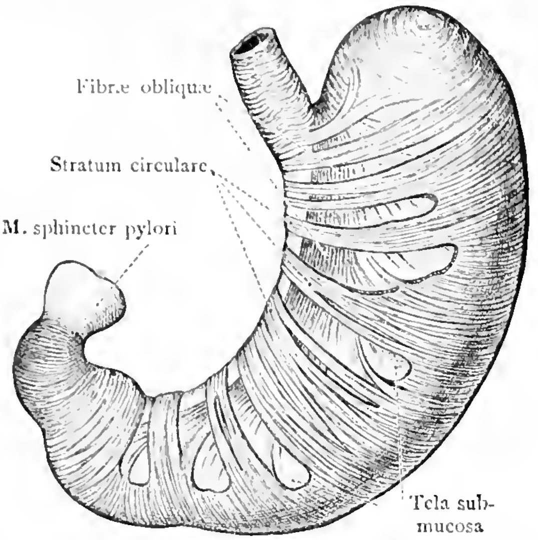

FIG. 4512. The Middle and Internal Layers of the Tunica Muscularis of the Stomach. Stratum circulare and fibræ obliquæ. The stratum circulare has been removed in places. (After C. Toldt, "Anatomischer Atlas," Zweite Auflage.)

along the lesser curvature is formed by the union of the right gastric branch (arteria gastrica dextra) of the arteria hepatica with the left gastric artery (arteria gastrica sinistra); that of the greater curvature, by the union of the right and left gastro epiploic arteries (arteriæ gastro-epiploicæ dextra et sinistra) derived from the hepatic and splenic arteries. In addition, the fundus ventriculi receives a number of short branches (arteriæ gastricæ breves) from the arteria lienalis. The large vessels formed by these anastomoses may be compared, according to Mall, to the vascular arches of the mesenteric arteries.

From the arches thus formed branches come off which penetrate the tunica muscularis at the curvatures, and are distributed in the tela submucosa of both surfaces of the organ. These branches in the submucosa are, in the dog, according to Mall, of various sizes, being smallest and most numerous in the pyloric region and fundus, largest in the middle zone. They pass in a circular direction around the stomach, branching and anastomosing freely to form a fine plexus of vessels, located at about the middle of the tela submucosa. From this plexus vertical branches arise which pass through the lamina muscularis mucosæ at very regular intervals and supply the mucous membrane. As soon as the bases of the glands are reached, each of these vessels breaks up into radiating branches (the stellate arteries), which in some animals form a second plexus within the deepest portion of the mucous membrane.

From these stellate arteries arise numerous capillaries which form a dense network with elongated meshes, surrounding the gastric glands from the bases to their necks. As the capillaries approach the openings of the glands, they begin to collect into larger vessels, which in turn communicate with a plexus of veins located under the epithelium. Thus the deeper layer of the mucous membrane receives the blood in a more arterial condition than do the superficial layers.

The subepithelial venous plexus is composed of small vessels which form a network of meshes surrounding the foveolæ near the openings. From this plexus larger veins pass vertically to join the subglandular plexus at the outer edge of the mucous membrane just internal to the lamina muscularis mucosæ. From this second venous plexus branches pass to the tela submucosa, which join one another and communicate finally with the submucous plexus of large veins. The veins which form the submucous plexus correspond in their distribution very closely to the vessels of the arterial plexus. Each large artery has, as a rule, two accompanying veins, the smaller arteries one. The arteries are, as a rule, more superficial than the veins and smaller in size.

The tunica muscularis is supplied, to a limited extent, along the greater and lesser curvatures by branches which come from the arteries as they pass through to the submucosa. The great bulk of the muscular coat, however, is supplied with blood by means of recurrent branches from the plexus of vessels in the submucosa. These branches pass directly outward from the submucous plexus through the stratum circulare, to the intermuscular layer, where they form a plexus the meshes of which are for the most part elongated in the direction of the fibres of the stratum longitudinale. From this plexus and from the recurrent arteries which form it are given off branches which break up into capillaries in the muscular layers. The circular coat receives, in addition, numerous branches directly from a plexus lying between the tela submucosa and the tunica muscularis.

All the veins leave the stomach in company with the arteries.

The lymphatics of the stomach begin as comparatively

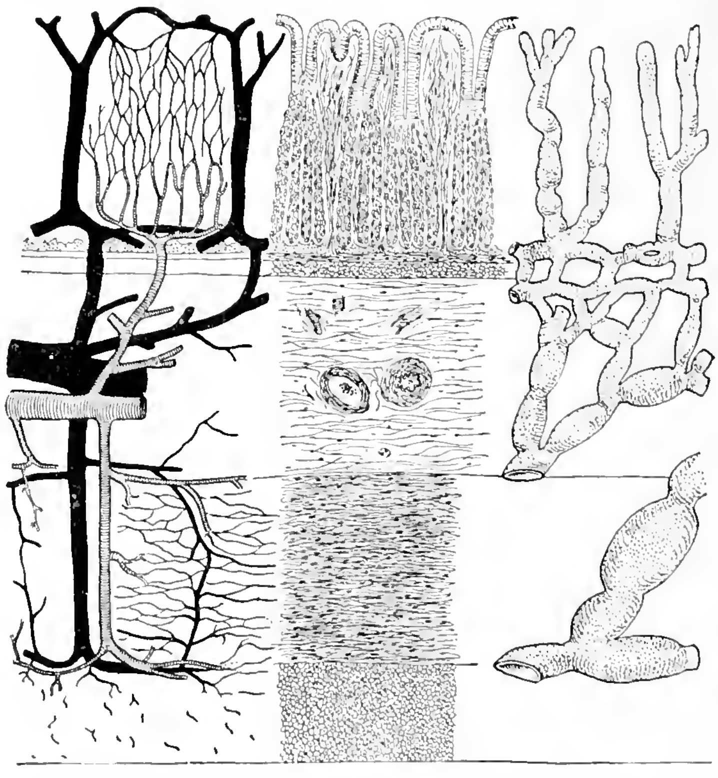

FIG. 4513. Three Sections of the Stomach Wall of the Dog, Placed Side by Side to show the Situation of the Blood and Lymph Vessels in the Different Tunics. × 70. Veins black; arteries striated; lymphatics dotted. (From A. Oppel, '96, after F. P. Mall.)

wide, blind, capillary tubes beneath the epithelium of the stomach. These pass somewhat irregularly outward and join to form larger trunks, which communicate with a fine network of lymphatic vessels located in the mucous membrane between the lamina muscularis mucosæ and the bases of the glands. This plexus (plexus mucosus) in turn communicates by means of vessels which pass at right angles through the lamina muscularis mucosæ with a second plexus located in the inner part of the tela submucosa. This plexus is composed of large vessels with many valves. From it arise many irregular branches which anastomose and pass through the substance of the submucosa to join the large collecting branches. The latter, in turn, communicate by large branches which pass through the circular muscle with the intermuscular plexus, the large vessels of which run toward the lesser curvature. For further details as to the arrangement of the large lymphatic vessels of the stomach, see the article on the *Lymphatic System*.

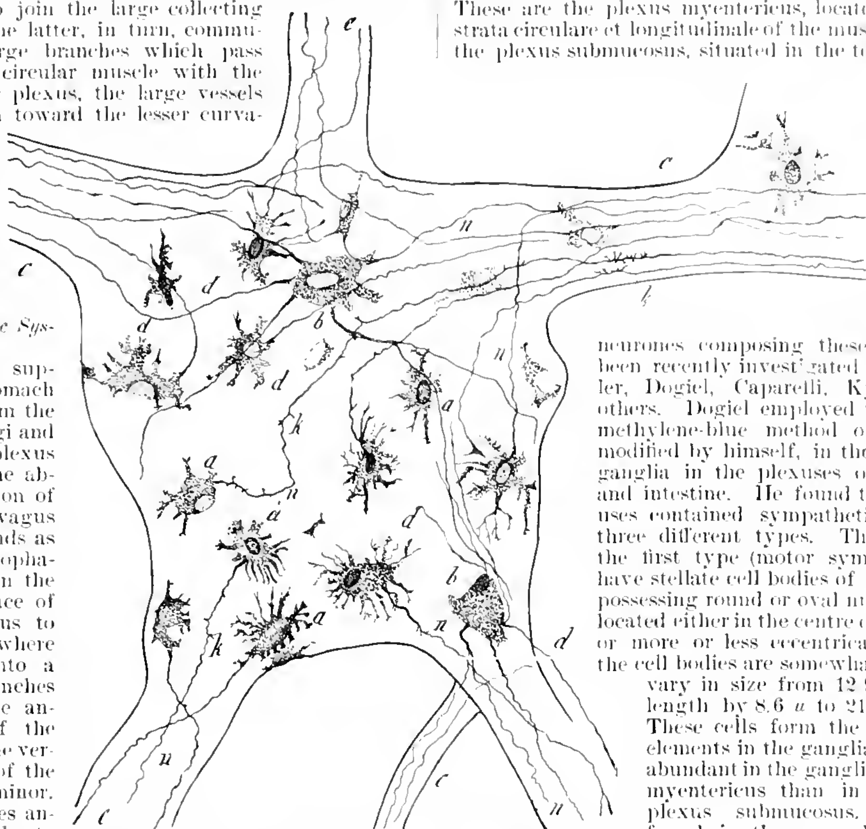

FIG. 4514.—Ganglion from the Plexus Myentericus of the Small Intestine of Man. *a*, Cell bodies of neurones of the first type (sympathetic motor neurones); *b*, neurones of the second type; *c*, nerve bundle. (After A. S. Dogiel, '99.)

The nerve supply of the stomach is derived from the two nervi vagi and from the plexus cœliacus. The abdominal portion of the nervus vagus sinister descends as the chorda œsophagea anterior on the anterior surface of the œsophagus to the stomach, where it divides into a group of branches located on the anterior face of the viscus, near the vertical portion of the curvatura minor. These branches anastomose freely to form the plexus gastricus anterior. From this plexus come off branches which radiate over the anterior face of the stomach. These branches run in the tunica serosa for a longer or shorter distance, but finally penetrate the muscular coats to terminate in the intrinsic plexuses of the organ. The right vagus goes in large part to the ganglion semilunare dextrum, but contributes some branches to the plexus gastricus posterior, distributed on the posterior face of the organ.

The sympathetic nerve supply is derived from the plexus cœliacus by means of fibres which accompany the several branches of the arteria cœliaca. The plexus gastricus superior accompanies the arteria gastrica sinistra, but also receives communicating branches from the right vagus, and from the plexus hepaticus, which reach the stomach in company with the arteria gastrica dextra. Some of the branches of the anterior gastricæ plexus accompany the rami œsophagei of the left gastric artery to the cardia; others descend upon the anterior and posterior surfaces of the stomach beneath the peritoneum, anastomosing on the left with the branches of the plexus lienalis which accompany the arteriæ gastricæ breves to the fundus, on the right with the branches of the plexus hepaticus which accompany the arteria gastrica dextra. Additional fibres from the hepatic and splenic plexuses accompany the arteriæ gastroepiploicæ dextra et sinistra respectively and are distributed to the greater curvature. The nerve fibres from all these sources, after a longer or shorter course in the tunica serosa, penetrate the muscular coats and join the intrinsic nerve plexuses of the organ.

The stomach, like the intestine, contains two characteristic nervous plexuses formed of branching and anastomosing bundles of non-medullated nerve fibres, forming a fine network with ganglia at the nodal points. These are the plexus myentericus, located between the strata circulare et longitudinale of the muscular coat, and the plexus submucosus, situated in the tela submucosa. The former plexus furnishes the motor supply to the tunica muscularis, the latter supplies the lamina muscularis mucosæ.

The structure of the neurones composing these plexuses has been recently investigated by Cajal, Müller, Dogiel, Caparelli, Kytmanow, and others. Dogiel employed the *intra-vitam* methylene-blue method of Ehrlich, as modified by himself, in the study of the ganglia in the plexuses of the stomach and intestine. He found that these plexuses contained sympathetic neurones of three different types. The neurones of the first type (motor sympathetic cells) have stellate cell bodies of angular shape, possessing round or oval nuclei, which are located either in the centre of the cell body or more or less eccentrically. Many of the cell bodies are somewhat flattened and vary in size from 12.9μ to 34.4μ, in length by $8.6\ \mu$ to $21.5\ \mu$ in width. These cells form the most frequent elements in the ganglia, and are more abundant in the ganglia of the plexus myentericus than in those of the plexus submucosus. A few are found in the nerve bundles which connect the ganglia with one another. From each pole of the cell body come off four to six or ten to twenty short, wide, somewhat flattened dendrites which a short distance from the cell subdivide into several more or less flattened short branches, which in turn divide and subdivide in a similar manner. According to Dogiel the terminal branches of these dendrites anastomose directly with similar dendrites belonging to other neurones of the same character. This direct continuity is, however, denied by La Villa and von Kölliker, who maintain that the apparent anastomoses seen by Dogiel are superposed but independent dendrites. Each of these neurones possesses, according to Dogiel, a single axone, which arises commonly from the cell body itself, but sometimes from a dendrite, by means of a thick cone of origin. This axone is a thin, smooth, or slightly varicose filament which traverses a greater or less extent of the ganglion and enters one of the connecting nerve bundles through which it courses to a second or third ganglion, in some cases even returning to the ganglion in which it took its origin. From this axone come off numerous extremely fine collaterals which leave the plexus in the groups of fibres distributed to the muscle coat. Finally, these axones break up into several fine varicose fibres which also terminate in the muscular layers, of which they appear to form the motor supply.

The neurones of the second type have somewhat larger cell bodies than the foregoing, and occur in much smaller numbers. Each cell body contains a moderately large, round, or oval nucleus with one or two nucleoli. From the poles of the cell body come off from three or four to as high as six or ten dendrites, which have the appearance of moderately thick fibres, and which presently divide into several thin branches. The latter do not terminate within the ganglion as do the dendrites and neurones of the first type, but enter the connecting nerve bundles, whence, after frequent subdivision, they pass into those small nerve bundles which traverse the stratum circulare tunicæ muscularis to connect the plexus myentericus with the plexus submucosus. In the latter, according to Dogiel, these dendrites may be often followed for considerable distances, and may be seen to pass into the mucous membrane, where they form the plexus of nerves surrounding the glands. The axone of the neurone of the second type begins in a more or less thick hillock on the cell body or on one of the dendrites and has the form of a nodulated, long, slightly wavy fibre, from which numerous collaterals similar to but shorter than the dendrites come off. The mode of ending of these collaterals and of the axone itself Dogiel does not describe, except to point out that the latter may be traced into the connecting bundles of fibres to a second ganglion.

The neurones of the third type resemble in many respects those of the second type. The dendrites form a richly branching system of very fine threads, which, in their finer ramifications, may be distinguished with difficulty from axones. These fine branches form a very rich plexus within the ganglion in which the cell body is located. The axones from these cells pass out by a nerve bundle to a second ganglion or to several successive ganglia. Their ultimate fate is unknown.

Among the nerve fibres ending in the ganglia, Dogiel distinguishes two kinds, one of which he regards as of sympathetic, the other of cerebrospinal origin. The fibres of the first kind are extremely thin, smooth, or slightly varicose threads, which do not differ in any respect from the axones of the neurones of the ganglia of the plexus. These fibres enter a ganglion by a nerve bundle, describe a more or less tortuous course among the nerve cells of the ganglion, and break up on their way into much thinner varicose fibrils, which in turn subdivide into a number of extremely fine end fibrils, which are beset with numerous round and oval varicosities. These end fibrils form an extremely close, intercellular plexus within the ganglia, without coming into direct contact with the cell bodies, from which they are always separated by the capsular cells. The second kind of fibres is distinctly coarser than the preceding and exhibits large, round, and spindle-shaped varicosities. In some cases Dogiel was able to trace these fibres through the longitudinal muscle coat and to demonstrate their continuity with medullated fibres. These fibres enter a ganglion from one of the connecting nerve bundles and may, in favorable preparations, be traced a considerable distance through the ganglion. In its course through the ganglion it gives off two to six or more varicose collateral branches, and ultimately breaks up into several similar fibrils. Both the collateral and the terminal branches go to the cell bodies of the ganglia, penetrate the capsules, and terminate in a number of fine varicose fibrils around the cells.

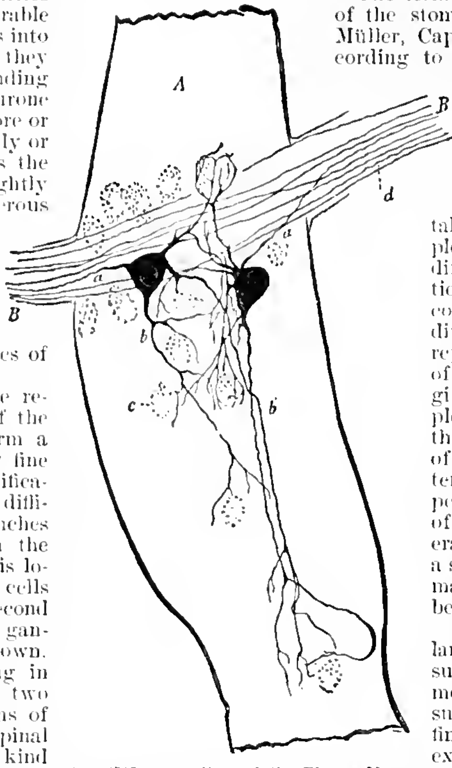

FIG. 4515.—Ganglion of the Plexus Myentericus of the Guinea-pig, showing the Cell Bodies of Neurones of Dogiel's Third Type. *a*, Axone; *b*, dendrites, some of which form a plexus around other cell bodies. (After A. S. Dogiel, '95.)

The stellate cells described by Cajal, Müller, and others, on the walls of the small blood-vessels and on the membrana propria of the glands, are regarded by Dogiel as connective-tissue cells.

As the foregoing description indicates, the exact relations of the nerve fibres which enter the stomach wall and of the axones and dendrites of the sympathetic neurones of the two principal plexuses, to the terminal organs in the walls of the stomach, are still doubtful, with the exception of the nerve supply to the muscle coats, which seems to be derived from the axones of the neurones of Dogiel's first type.

The terminations of the nerves in the walls of the stomach have been studied by Berkley, Müller, Caparelli, Kytmanow, and others. According to Müller, who employed the rapid Golgi method in the study of the nerves of the stomach and intestine, the muscular coats contain an extremely large number of nerve fibres, partly in the form of end fibres, partly as larger or smaller nerve bundles. These take their origin from branches of the plexus myentericus, which run in a direction at right angles to the direction of the muscle fibres. From these come off branches which follow the direction of the muscle fibres. The repeated subdivision and intercrossing of the branches of these nerve bundles give rise to a very fine intramuscular plexus of fibres. The termination of the fine terminal twigs takes the form of a group of branches, each of which terminates in a minute spherical or pear-shaped swelling on the surface of a muscle cell. There may be several of these swellings in the course of a single terminal nerve filament, which may thus supply successively a number of muscle fibres.

A plexus of fine nerve fibres, to a large extent derived from the plexus submucosus, exists in the mucous membrane. Cacciola distinguishes a subglandular plexus and a plexus of finer fibres surrounding the glands and extending as far as the free surface of the mucous membrane.

According to Müller the nerves terminate by free, often swollen extremities, under the cylindrical epithelium, or between the pointed proximal ends of the cells. Kytmanow, using the methylene-blue method, was able to trace the nerve terminations through the basement membrane into the glands, where they terminate by each dividing into a group of coarsely varicose filaments, which penetrate between the cells of the glands and lie in close contact with both the surfaces of the parietal and chief cells.

The stomach is developed as a spindle-shaped dilatation of the primary endodermal canal, which may be recognized in very early embryos. The stomach is at this early stage vertical and median in position. In embryos of 5 mm. length there is already an indication of the greater and lesser curvatures, and in the 12.5 mm. embryo these are well formed, the greater curvature being directed backward and slightly toward the left; the lesser curvature forward. Owing to the increase in length of the œsophagus and stomach, the latter has descended from its primary position above the septum transversum into the abdominal cavity. The stomach at this stage is connected with the abdominal walls both dorsally and ventrally by a double layer of mesoderm, forming the mesogastrium anterius and the mesogastrium posterius. The former extends from the septum transversum to the umbilicus and contains between its two layers the developing liver, of which it subsequently forms the tunica serosa. The portion of the mesogastrium anterius between the liver and the anterior abdominal walls forms the falciform ligament (ligamentum falciforme hepatis); that between the liver and the lesser curvature of the stomach becomes the lesser omentum. The final position of the stomach is reached by a gradual shifting of the upper end of the organ from its median position toward the left side, and a rotation of its axis in such a way that the primary right side of the stomach becomes the posterior face, the primary left side the anterior face; and the fundus of the stomach becomes directed to the left. During this process the mesogastrium posterius undergoes a more rapid development than is necessitated by the changing position, forming an elongated pouch, which hangs down ventral to the rest of the intestine, and forms the great omentum (omentum majus). The portion of the cœlom enclosed between the two layers of the elongated mesogastrium posterius becomes the lesser peritoneal sac, or bursa omentalis.

From the visceral layer of the mesoderm are developed the three outer layers of the wall of the stomach as well as the tissue of the lamina propria mucosæ. The epithelial elements of the stomach, including the gastric glands, are derived from the endoderm.

The development of the gastric glands has been investigated by Kölliker, Laskowsky, Brand, Toldt, Sewall, Salvioli, Ross, and others. On account of the difficulty of obtaining human material in a sufficiently good state of preparation, most of the work along this line has been done on the stomachs of lower mammals.

According to Toldt, the endodermal layer of the stomach in the cat embryo of 2.5 cm. body length is still composed of a single layer of small pyramidal or conical cells, the nuclei of which are placed at different levels. Of these he recognized two kinds: one of these has its broader end directed toward the inner surface of the stomach and contains a large oval nucleus near the free border; the other kind of cell has the broader base directed toward the attached side of the epithelium. Both of these cells extend through the whole thickness of the epithelium, which is thus unstratified, though he points out that in poorly preserved material the impression of stratification might easily be obtained. In somewhat older cat embryos, up to 5 cm., the condition is much the same, except for the greater number of cells of the second type mentioned above in the epithelium. In cat embryos from 5 cm. body length upward, the structure of the epithelium is modified by the appearance in it of the rudiment of the gastric glands. Concerning the formation of the latter two views exist. According to one group of observers, including Kölliker, Brand, and Sewall, the determining factor in the formation of the gastric glands is the irregular growth of the mesodermal stratum. This, according to Brand, is accomplished by the growth of villus-like processes covered with epithelium. By the coalescence of the bases of these villi shallow pits are formed which are the rudiments of the glands. A similar description of the origin of the glands is given by Sewall, except that he describes the gland processes as short ridges instead of villi. According to Toldt and Ross, the formation of villi has nothing to do with the development of the glands, which they regard as wholly intra-epithelial in origin. Toldt recognized the rudiments of the glands in cat embryos of from 5.3 to 6.8 cm. body length in the form of single scattered cells of spherical or ellipsoidal shape located between the bases of the cylindrical cells, which at this stage make up the gastric epithelium. In addition to their characteristic location, these cells are distinguished from the other cells by their coarsely granulated protoplasm and greater opacity. In places several such cells could be seen so grouped together as to leave little doubt that they had arisen by division of the single isolated cell. Such groups often contained a minute circular vacuole-like space, the future lumen of the gland. This group of cells assumes gradually, by increase of its elements, an elongated shape, and an opening to the surface is obtained by displacement of the overlapping cylindrical cells. The displacement of the bases of the latter by the growing gland rudiment causes the inner ends of the epithelial cells immediately surrounding the gland to converge toward the opening, forming in this way the first indication of the gastric foveola. The further development of the glands consists in the increase in length and number of the gland tubules and the differentiation of their specific glandular elements. The increase in length of the glands soon causes them to project beyond the epithelial layer into the subjacent mesoderm. The increase in number of the glands in the course of development is accomplished in part by the formation of new glands in the epithelium, in part by the branching and subdivision of those already existing.

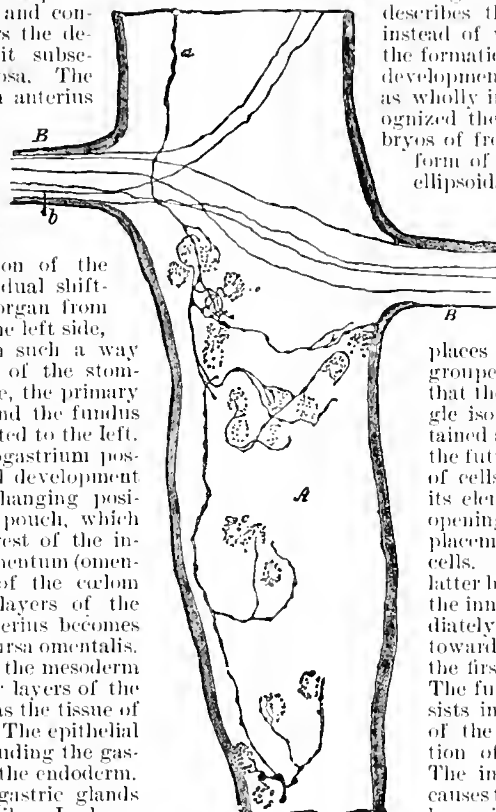

FIG. 4516.—*a*, Nerve fibres of Dogiel's second type which end in a ganglion of the plexus myentericus (guinea-pig) in pericellular groups of branches; *A*, ganglion; *B*, nerve bundle. (After A. S. Dogiel, '95.)

The differentiation of the specific cellular elements of the glands occurs, according to Toldt, at a somewhat late stage of development. In cat embryos of 13-14 cm. body length—that is, shortly before birth—he found the majority of cells forming the glands still undifferentiated. In the deeper part of the glands, however, a few larger richly granular parietal cells could be seen.

The recent account of the development of the gastric glands, given by Ross, practically confirms Toldt's observations in all essential details. These two observers are agreed as to the non-participation of the villus-like ridges of the developing stomach in the formation of the glands.

STOMACH AND ŒSOPHAGUS. (SURGICAL.)—I. THE SURGERY OF THE ŒSOPHAGUS.—*Methods of Examination.*—The *x* rays are very useful in locating bone; also coins and other metallic foreign bodies. It is usually best to take a skiagraph, in order to determine the exact relations of the foreign body. The fluoroscope is occasionally very useful, and the surgeon may sometimes even attempt to extract the foreign body with forceps while he looks through the fluoroscope. An œsophageal diverticulum may be shown by the *x*-rays, if the patient has previously swallowed capsules of subnitrate of bismuth. If the bismuth enters the diverticulum, it will coat it so that the pouch will cast a shadow in the *x*-rays. A bougie containing a piece of metal on a small metallic chain may, in some cases, enter the diverticulum and cast a shadow with the *x*-rays.

The most common method of examining the œsophagus is with the exploratory sound. A flexible bougie with an ivory tip will locate an obstruction, whether it be a foreign body or a stricture. In an adult, it is best to make an examination of this kind without ether. If ether is not employed, we can keep the patient sitting up; and he can help us by swallowing the instrument when directed to do so, and can also aid us somewhat in locating the obstruction. In a child, it may be necessary to give an anæsthetic. The bougie should be passed as follows, when the patient is not anæsthetized:

He sits up and rests his head against a chair-back, a bed-rest, or the chest of another person. The surgeon stands in front of him. The patient's head is thrown back and held securely by an assistant. When the patient is a child, it will be necessary to hold the arms also. The mouth may be gagged open with a bit of wood or a cork, but I usually dispense with a gag and simply wrap the forefinger which is to be inserted with some gauze. The instrument is warmed and smeared with glycerin, and is passed into the rear of the pharynx, the surgeon drawing the tongue forward and holding it with a towel. Drawing the tongue forward draws the larynx a little forward also, and enables the instrument to pass more readily over the glottis. In some cases it is necessary to guide it over with the index finger of the left hand.

As soon as the instrument strikes the back of the pharynx, the patient will attempt to vomit; but the slight respiratory obstruction met with here should not deter one, although, of course, if there is violent respiratory difficulty the instrument must be at once withdrawn, because of the fear that it may have entered into the larynx. After it strikes the back of the pharynx it should be pushed on steadily but lightly, and the patient should be directed to swallow. The passage of the instrument will thus be greatly aided. When the instrument is blocked by an obstruction, one must not attempt to force it, but should hold it gently in contact with the obstruction. If this is only spasmodic, the spasm may relax and let the instrument pass. If the obstruction is organic, it will not relax. We should always remember, however, that an organic stricture may be associated with a spasm above it, and therefore that we may be blocked by spasm before reaching the true seat of disease. If we are in doubt as to whether we are dealing with a pure spasm or with an organic stricture, the administration of an anæsthetic will solve the doubt; for a pure spasm relaxes when the patient is anæsthetized, so that the instrument is allowed to pass, but an organic stricture does not relax. The average distance from the incisor teeth to the cardiac opening of the stomach in the adult is, according to Maylard, from fourteen to sixteen inches.

The *œsophagoscope* (Fig. 4518) has been used for many years by Mikulicz, but it is only of late that its real value has become recognized by the profession at large. In fact, in this country the appreciation of this seems to date from the visit of Gottstein, Mikulicz's assistant, about a year ago. The œsophagoscope is undoubtedly a useful instrument. With its aid one may see a tumor, an ulcer, a foreign body, varicose veins, or a strictured area; and may remove in some cases a foreign body and in others a tumor for examination. Of course, in order to use the instrument well a man must be specially trained, and good results can be obtained only by an expert; but the same assertion is true of the use of the ophthalmoscope, the laryngoscope, and the cystoscope. Any one can learn to use the œsophagoscope, but only an expert will use it really well. One great lesson in its use is to be very gentle and never to force it, and, if it is obstructed by spasm, to wait for the spasm to subside before urging it onward.

When one has decided to use this instrument, he should first employ a sound to locate the situation of the obstruction. The pharynx, the larynx, and the upper part of the œsophagus are then cocainized with a ten-per-cent. solution of cocaine. The patient lies upon the table, on his right side, the clothing about his neck and his chest being loosened. His head rests upon a pillow, being bent back so far that a straight line through the mouth would enter into the œsophagus. He is told to raise his left hand if he feels pain and wishes the instrument withdrawn, and he is ordered to breathe quietly and regularly. Then the tongue is drawn forward and the tube is introduced into one side of the mouth and carried into the pharynx. As the patient swallows, the instrument passes down to the desired point. Then the plunger is withdrawn and the panelectroscope is inserted, throwing light to the bottom of the tube. Any mucus present is swabbed away with pieces of gauze caught in forceps; the region of disease is carefully studied, and, if thought desirable, a piece of tumor is removed. A note on the use of this instrument may be found in *American Medicine*, October 25th, 1902, in the editorial comment on general surgery; and the instrument is fully described by Gottstein in his "Technik u. Klinik der Oesophagoscopie."

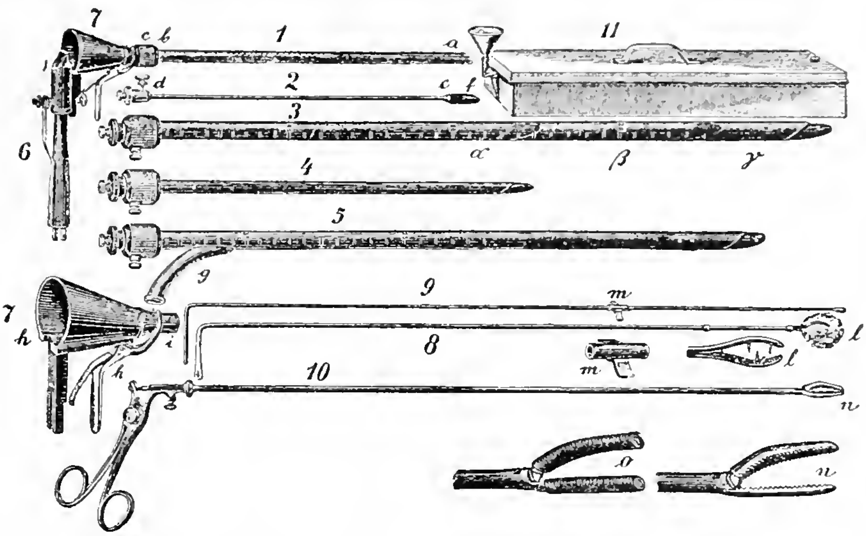

FIG. 4518.—Gottstein's Œsophagoscope. *1*, Œsophageal tube with oblique end (*a*), with hard-rubber ring (*b*), with bayonet catch (*c*); *2*, mandrel for the tube with screw at the upper end (*d*), fitting into the bayonet catch, and a hard-rubber olive point at the lower end (*e*), bevelled on the side (*f*); *3*, œsophageal tubes of different lengths (26, 36, and 46 cm.) and 14 mm. in diameter; *4*, children's size of tubes, 10 mm. in diameter; *5*, tubes with outflow tube (*g*) at the upper end; *6*, Casper's panelectroscope; *7*, the intermediate piece between the tube and the panelectroscope—external end (*h*), internal end (*i*), handle for detaching it from the tube (*k*); *8*, sponge-bearer with double teeth (*l*); *9*, sound with a rider (*m*); *10*, forceps with rough jaws (*n*), or covered with rubber (*o*); *11*, hot-water pan.

OPERATIONS ON THE ŒSOPHAGUS.

Internal Œsophagotomy.—By this operation one divides a fibrous stricture. The method of performing it is to pass an instrument known as an œsophagotome. In order that this may be passed, the channel of the stricture must be large enough to admit the instrument. After the latter has passed through the stricture, the blade is protruded and the instrument is withdrawn. From forty-eight to seventy-two hours after the operation, the surgeon begins to effect distention by means of bougies. Gussenbauer performs internal œsophagotomy by making an opening in the œsophagus above the stricture, and then, through this opening, cutting the stricture by means of a tenotome. Internal œsophagotomy may be productive of dangerously severe hemorrhage and is occasionally followed by infective processes—for instance, by empyema. It should never be attempted for malignant obstruction.

Electrolysis.—Electrolysis has been much improved by Fort and others. It should not be used for malignant obstruction, but may be of great benefit in cicatricial stricture. It will fail, however, if the stricture is very hard. It is probable that several applications will be necessary in most cases, after which bougies should be used for a considerable length of time.

External Œsophagotomy.—External œsophagotomy may be performed through the neck by what is known as cervical external œsophagotomy; or it may be performed through the mediastinum—the intramediastinal method. External œsophagotomy may be done for the purpose of treating a cicatricial stricture of the œsophagus, either directly—as in Gussenbauer's method—or indirectly—as in Abbe's string-saw method. It may also itself directly divide a stricture. The chief use of the operation, however, is to remove foreign bodies, when these are lodged above the lower third of the œsophagus. If the foreign body has been in the œsophagus over twelve hours and has sharp edges, attempts to extract it through the mouth should not be made, but external œsophagotomy should be performed at once.

The incision is usually made on the left side, the cut being at the anterior edge of the sterno-cleido-mastoid muscle, and running from half an inch above the sterno-clavicular joint to the level of the superior border of the thyroid cartilage. The muscles are retracted, in some cases the omohyoid is divided, the trachea is drawn forward, great care is taken to avoid the recurrent laryngeal nerve, and the gullet is exposed. If a foreign body is palpable, the incision is made upon it; otherwise a bougie is introduced, and the gullet is opened upon that.

After the foreign body has been removed, there is a question as to how the wound should be managed. It seems certain that it should not be closed without any drainage. In fact, some surgeons do not close it at all, but simply pack it with gauze. It is wiser to suture the mucous membrane with stitches of silk or chromicized catgut, to run a piece of gauze down to the suture line for drainage, and then to suture the muscles and the skin, the gauze drain being removed within two or three days.

For the first twenty-four hours after the operation the patient is given no food by the mouth, but is fed by the rectum; and rectal feeding is continued as a supplement to mouth feeding until sufficient food can be taken by the mouth to meet the needs of the organism. After twenty-four hours small amounts of liquid may be given by the mouth, and more and more should be given each day until the full quantity can be taken. Frequently there is a little leaking through the mucous membrane.

FIG. 4519. — Coin-Catcher and Sponge probang.

Intramediastinal Œsophagotomy.—Weir, Quenu, Rehn, and others have given much thought to the matter of reaching dense strictures below the arch of the aorta. Rehn endeavored to reach such a stricture by a posterior operation, but he found the difficulties and dangers to be insurmountable. He made an incision over the angles of the ribs, between the inner edge of the scapula and the spines of the vertebræ, resected parts of several ribs, separated the pleura, and felt for the œsophagus. At the present time the operation does not seem justifiable.

Œsophagostomy.—In this operation the œsophagus is exposed and opened as in cervical œsophagotomy, but the edges of the œsophageal opening are sutured to the skin. A tube, somewhat resembling a tracheotomy tube, is inserted and tied in place; and when one desires to feed the patient, a long tube of less diameter than the retained tube is passed through the latter into the œsophagus.

Excision of Diverticula.—I have never performed this operation, but have assisted Professor Hearn to perform it. Whenever possible, a bougie should be carried into the sac. Then ether should be given, and the sac exposed and tied off with a catgut ligature. The sac is extirpated beyond this ligature and the stump is sutured. In Dr. Hearn's case the diverticulum was cut off, the mucous membrane was sewed with a continuous suture of catgut, the muscular layer was closed with interrupted sutures of silk, a piece of gauze packing was carried down to the mucous membrane, and the other tissues were sewed with silkworm gut. No leaking took place, and the wound completely healed within twelve days. Several other cases have been reported.

Œsophagectomy.—By this term is meant the resection of a portion of the œsophagus. In the cervical operation an incision is made in the neck to expose the œsophagus, and this incision is identical with that for internal œsophagotomy. After the gullet has been exposed, it is separated completely from the surrounding parts, the diseased area is excised, and the lower end of the gullet is sutured to the skin. This is a very difficult operation, and is of questionable utility.

De Quervain has performed this operation in one case, and has collected thirteen other cases from literature. He maintains that the operation is justifiable in some cases, viz., those in which there is malignant disease involving the œsophagus only, and in which the lower margin of the growth is above the aorta and the upper margin is at least 20 cm. from the teeth.

Occasionally, though rarely, a preliminary œsophagostomy may be performed, but preliminary gastrostomy is much to be preferred to preliminary œsophagostomy. When a preliminary gastrostomy is performed, healing of the œsophagus is greatly favored. When preliminary gastrostomy has been performed, and œsophagectomy is carried out whenever it is possible, the upper end of the lower part of the gullet should be sutured to the wound; but if this cannot be done, a ligature should be tied about that part of the œsophagus, and it should then be dropped back into the wound.

This author maintains that the patient is much better off with a gastric fistula than with a contracting cicatrix of the gullet, which will be sure to establish itself if the ends are brought together. In cases in which the ends cannot be brought together, there will, of course, be a salivary fistula from the upper end of the œsophagus (*Arch. f. klin. Chir.*, 1898, Bd. lxviii., Hefte 1-4). By some surgeons an attempt has been made to extirpate the œsophagus by what is called endothoracic resection; but at the present time the operation is not to be recommended.

Œsophagoplasty.—After a portion of the œsophagus has been resected for cancer, an attempt may be made to reconstitute the canal by von Hacker's method of œsophagoplasty. Maylard describes this operation as follows: "The operation is performed in two stages. After excision of the part, two flaps of skin are raised on each side. These are carried backward and united above and below to the cut ends of the œsophagus. This constitutes the first stage. The second consists in detaching these flaps from their bases and folding them over, so as to complete the canal. The stitching is completed around the œsophagus, above and below, and they are united together down the median line" ("The Surgery of the Alimentary Canal," by A. Ernest Maylard).

Foreign Bodies in the Œsophagus.—When a foreign body has passed into the œsophagus, the surgeon should endeavor to obtain information as to its size, its nature, its shape, and its weight; and he should then seek to locate its point of lodgment. The point at which a bone or a metallic body has lodged may be determined by using the *x*-rays; the location of other kinds of foreign bodies by using the œsophageal sound; and the position of both classes of articles by using the œsophagoscope. In employing the sound it may be necessary to give ether; this is seldom required for an adult, but usually for a child, a nervous woman, or a lunatic.

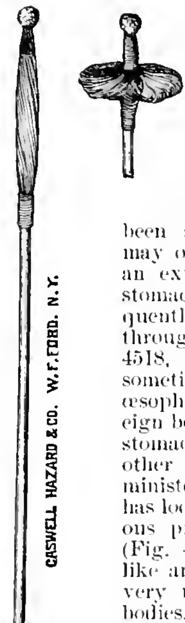

FIG. 4520.—The Bristle or Umbrella Probang.

When a soft foreign body has been swallowed, external manipulation may occasionally alter its shape to such an extent that it will pass on into the stomach or be coughed up. Not infrequently the foreign body may be reached through the mouth with forceps (Fig. 4518, 10), and these manipulations are sometimes much aided by employing the œsophagoscope. Small and sharp foreign bodies may often be carried into the stomach by swallowing mush, bread, or other food of a similar nature. To administer an emetic when a foreign body has lodged in the œsophagus is a dangerous procedure. The horse-hair probang (Fig. 4520) is an instrument that opens like an umbrella as it is withdrawn; it is very useful in extracting some foreign bodies. The coin-catcher (Fig. 4519) is also a very useful instrument. Occasionally, when it is impossible to pull a foreign body up through the mouth, it is advisable to push it down into the stomach. This may be done with such a body as a small coin that, we feel sure, will ultimately pass through the intestinal canal.

It is never proper to permit a foreign body to remain in the œsophagus until ulceration occurs; neither is it right greatly to prolong efforts to extract a foreign body through the mouth, and such efforts should not be made at all if ulceration is believed to exist. When a patient has a foreign body lodged in the œsophagus, and there is no ulceration, the surgeon should make one careful and thorough attempt to remove it through the mouth; and if this attempt fails, he should at once proceed to operate. If he thinks that ulceration exists he should operate. Long retention means probable ulceration.

If the point of lodgment is anywhere within the upper two-thirds of the œsophagus, external œsophagotomy should be performed; if it is in the lower third, the stomach should be opened. Then either the foreign body

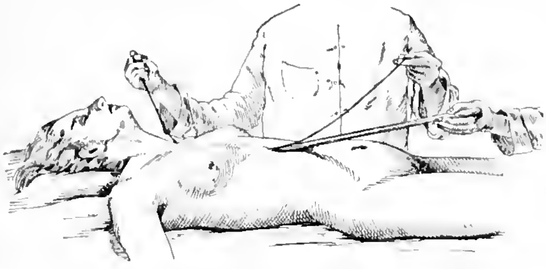

FIG. 4521.—Abbe's String-saw Operation. Method of using the bougie and string. (Abbe.)

should be drawn down into the stomach and thus removed, or else a whalebone bougie should be passed from the mouth into the stomach, a string should be tied to the bougie, and pieces of fluffed-up gauze should be fastened to the string. As the string is pulled, the foreign body is extracted. If the bougie cannot be passed from the mouth into the stomach, it may perhaps be carried from the stomach into the mouth.

Cicatricial Stricture of the Œsophagus.—In almost every case—at least for a certain length of time—gradual dilatation is employed, the largest bougie that will readily pass being used. The bougies with olive-shaped tips are not used, but the conical semisolid elastic instruments are employed. The bougie should be retained for several minutes and should be passed every second or third day. Each time it is passed it should be retained in the stricture longer than on the preceding occasion. As soon as it is found that the instrument begins to pass easily, a larger one should be employed. Gradual dilatation will be successful only if the stricture occupies a limited portion of the œsophagus.

Symonds inserts a tube through the stricture, leaves this in place until it becomes loose, then inserts a larger tube, and so on, the patient being fed through the retained tube. In some cases, when gradual dilatation from above is impossible, a gastric fistula is made, the patient swallows a shot to which a silk thread is fastened, the thread is brought out through the fistulous opening in the stomach and fastened to a bougie, and the dilating instrument is drawn up through the œsophagus.

I have already pointed out that a cicatricial stricture of the œsophagus is often associated with swelling and spasm, and that if a gastrostomy is performed the swelling and spasm abate, because of rest. In this way a stricture previously impassable may become passable. Some surgeons have employed forcible dilatation by way of the mouth or through an opening in the stomach. Electrolysis is used by Fort and some others.

We have already discussed the operations of internal and external œsophagotomy. If there is a dense stricture in the thoracic portion of the œsophagus, and this stricture is not dilatable, one should treat it by Abbe's method. Abbe performs gastrotomy, passes a conical rubber bougie carrying a silk thread from the stomach into the mouth. The end of the string is grasped and withdrawn, the stricture is made tense by introducing a conical bougie from below, and the string is drawn tight. One end of the silk emerges from the mouth and is carried back into the pharynx, and the other end comes out of the opening in the stomach. The string is moved rapidly to and fro and divides the stricture. After the division of the stricture, the silk is withdrawn and full-sized bougies are passed. In some cases Abbe opens the stomach and also the œsophagus above the stricture, and brings one end of the string out of each wound (Figs. 4521 and 4522).

Ochsner has devised an operation in which he draws a small, soft-rubber drainage tube, caught up in the middle with a thread, through the stomach wound and into the stricture. When traction is made upon this tube it becomes smaller; and it is made smaller by traction until its size is sufficiently diminished to allow it to enter the strictured portion of the œsophagus. The tube is drawn out by its free ends, and increasing sizes of tubes are employed.

Carcinoma of the Œsophagus.—This disease is necessarily fatal. Operations done for it are really only palliative, as œsophagectomy is not a satisfactory procedure. The patient is given a soft, bland diet, in small quantities at a time and very often. When there begins to be distinct trouble in swallowing even this food, a soft bougie should be carefully passed every third or fourth day, or a Symonds tube should be inserted; or œsophagostomy may be performed below the growth, if this is possible, or gastrostomy should be done.

II. SURGERY OF THE STOMACH.—The operative surgery of the stomach is to a very great extent distinctly modern, although gastrotomy has now and then been performed from time immemorial, and gastrostomy was practised as long ago as the time of Sedillot. The direction of surgical thought toward operative possibilities in this region seems to have begun in 1875, when many experiments upon animals were made to show that resection of the stomach is a thoroughly possible operation. It was in 1876 that Gussenbauer and Winiwarter made a series of experiments upon dogs, and maintained that the surfaces of the stomach, when sewed together, have a tendency to heal by first intention, and, further, the very important fact that the mucous membrane near the wound is not digested by the gastric juice. They resected the stomachs of seven dogs, and, as Dr. Keen says in his Cartwright Lectures, showed that a partial resection may be successfully accomplished; that the resulting stricture does not interfere with the motor or secretory power of the stomach; and that pyloric resection does not permit of a too early escape of food into the intestine, or of the regurgitation of the intestinal fluids into the stomach. Kaiser and, shortly after, Gussenbauer performed gastrectomy upon dogs, and obtained better results than their predecessors because they employed antiseptic methods with more care (Arthur E. Barker).

These and numerous other experiments upon animals have not only indicated that extensive operations may be performed upon the stomach with the retention of life and the repair of damage, but have pointed the way to the various refinements of technique that are found to be such valuable accessories in securing a successful result. In this field of surgery the principles of Lister have secured a notable triumph.

The above-cited experiments gave a stimulus to human visceral surgery, and in 1877 Billroth successfully sutured

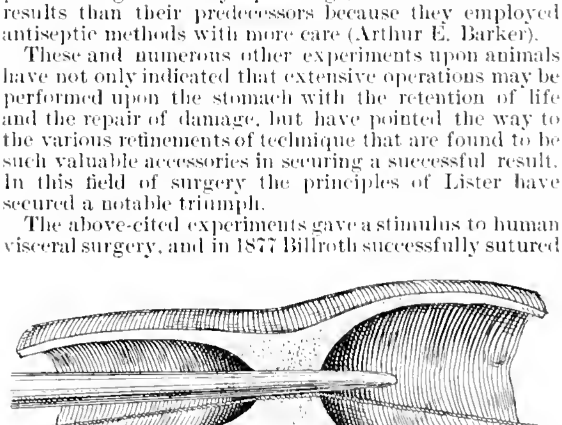

FIG. 4522.—Abbe's String-saw Operation. String dividing the œsophageal stricture kept tense by bougie. (Abbe.)

a wound in the stomach. From that time to this stomach operations have multiplied, until it is now considered proper to open the stomach, not only for the removal of foreign bodies or to secure ingress for food by a permanent artificial mouth when there is obstruction of the œsophagus or of the cardiac end of the stomach, but also to remove ulcerations, to separate constricting adhesions, to extirpate malignant tumors, to arrest hemorrhage, to side-track a malignant tumor or a fibrous constriction by the operation of gastro-enterostomy, to diminish the size of a distended stomach by placing numerous tucks in its wall, and even to remove the entire stomach—any of which operations may be done with the retention of life and digestive capacity. The number of cases of disease of the stomach in which operation is now performed is simply amazing, and may be especially gathered from a study of the reports of Professor Mikulicz, of Breslau; Professor Weir, of New York; Dr. Doyen, of Paris; Dr. Mayo, of Rochester, Minn.; Mr. A. W. Mayo Robson, of Leeds, England; Professor Keen, of Philadelphia; Prof. Arthur E. Barker, of London, and many others.

The surgery of the stomach may be presented to the reader in two ways: First, by describing in detail the different operations upon the stomach and setting forth the morbid conditions to which they should be applied; and, secondly, by discussing the surgical treatment of certain diseases of the stomach. In an article such as this, neither of these methods can be followed purely; it will be necessary first to discuss a number of the particular operations, and next to consider the surgical treatment of certain special conditions.

The operations to be considered are.

1. Gastrorrhaphy, or the suturing of a wound or a perforation in the stomach.

2. Gastrolysis, or the separating of perigastric adhesions.

3. Gastropexy, or the lifting of a stomach that has dropped downward, and the fastening of it in a normal position.

4. Gastroplication, or the diminution of the size of a dilated stomach by making tucks in its wall.

5. Gastrotomy, or incision of the stomach, followed by the subsequent closing of the wound.

6. Gastrostomy, or the making of a more or less permanent opening into the stomach—an opening that is usually employed for the purpose of administering food.

7. Gastro-enterostomy, or the making of a permanent opening between the stomach and the duodenum or the ileum.

8. Gastrogastrostomy, or the making of a permanent opening between two portions of the stomach itself, when there is a constriction existing between the two portions; and gastroplasty, an operation performed for the same purpose and similar to pyloroplasty.

9. Pyloroplasty, a procedure for enlarging the calibre of a strictured pylorus.

10. Gastrectomy, or the excising of the stomach wall—called partial gastrectomy when a portion of the wall is removed, and called complete gastrectomy when ablation of the entire stomach is practised.

11. Pylorectomy, or the excising of the pyloric end of the stomach and of the gastric end of the duodenum.

12. Jejunostomy, the making of a permanent fistula in the jejunum.

1. *Gastrorrhaphy.*—The term gastrorrhaphy should really be employed only to mean the suturing of a wound or perforation of the stomach wall. It has, however, been employed as synonymous with gastroplication, a usage of the term that is very objectionable.

A wound in the stomach is more easily managed and can be more firmly and securely closed than can a wound in the intestine. The blood supply, as Dr. Mayo points out, is excellent, and is derived from different sources; the mucous membrane of the stomach is thick. The stomach is fairly well fixed, the gastric juice is antagonistic to bacteria and the sutures can be firmly placed and are not apt to cut out. In doing this, it is necessary to bear in mind certain general principles:

The needle that is employed should be fine and round, and not one with a spear shaped or an edged point. A flat needle is very objectionable.

Fine sterile silk is the best suture material. Whereas it is permissible to use catgut to close the mucous membrane, it is not proper to use catgut to close the wound in the other coats. Strong gut is too large in diameter, it may be wiry and may cut when tied, it swells more or less after insertion, the stitch holes may leak, and it is of doubtful cleanliness; it is, therefore, an improper material.

Some surgeons advocate first closing the mucous membrane by means of a continuous suture of catgut. This method has its advantages. If this is done leakage in the suture line of the outer coats is prevented for many hours after the operation. Some have maintained that it is objectionable to use a mucous-membrane suture at all, because it may permit of infection of the coats beyond it and prevent the satisfactory drainage of an infected suture line. As a rule, it is satisfactory to close the stomach wound simply with inversion sutures of silk; but Halsted's plan is safer. Inversion sutures are caught in the submucous coat, but do not penetrate the mucous membrane. They should be about one-sixth of an inch apart; and when the ordinary Lembert stitches are used, it is advisable to employ from two to four layers of them, in order to secure an unleaking suture line. Whenever possible, these sutures should be introduced in the direction in which the blood-vessels run. Before tying them some surgeons scarify the peritoneal surface of the wound edges, believing that by so doing they expedite union. It is not necessary to trim the edges of a bullet wound or of a perforated ulcer, because the area of contusion or thrombosis can, in such cases, be deeply inverted and closely covered over.

The knots are tied firmly, but never tightly. To tie them tightly means either that there will be some cutting of the suture, or that there will be subsequent necrosis about the stitch hole, with loosening of the suture and probable infection. I believe that tying stitches too tightly is a most powerful predisposing cause of wound infection.

Interrupted sutures are better than the continuous suture; and the continuous inversion suture should not be used, except as a final stitch over previous layers of interrupted sutures. The continuous suture makes irregular lines of traction and unequal apposition of surfaces. If one part breaks or loosens, the whole suture line gapes, and there is much greater probability of leakage than when well-applied interrupted sutures are used.

Halsted's principle of suturing is the correct one; that is, that each stitch must catch up a portion of the fibrous submucous coat. The Halsted mattress sutures, when applied with care, will certainly approximate the margins of a stomach wound so that they will give broad surfaces for union, and will make such even pressure and give such thorough closure that even a single line of sutures is practically safe. Professor Halsted has employed the following method with great satisfaction for many years: When feasible he uses three rows of sutures. The inside row is continuous and includes the mucosa and submucosa and the edge of the serosa. The middle row is continuous, interrupted here and there. The outside row is made with mattress sutures. In other words, Halsted uses the Czerny suture with an outside row of mattress sutures. Halsted's method is the safest and hence the best. The various sutures that may be used upon the stomach will be found described in detail in the article on *Intestinal Surgery*. The chief of these are the Lembert suture, Cushing's right-angle suture, Gussenbauer's suture, Czerny's suture, Wölfler's suture, Bishop's suture, and Halsted's mattress suture.

When a gap in the stomach wall is too large to invert, or when, because of great thickness of the edges of the opening or of the existence of dense encompassing adhesions, the edges cannot be turned in, some other course must be followed. In some cases union has been secured by first suturing the mucous membrane and then the other layers of the stomach wall, just as we would suture an ordinary wound, without inversion. Another method, and a better one, is to use such a suture and then cover the suture line, after the plan of Senn, with a portion of omentum that is still left attached to the great mass of the omentum, or with a separate omental graft. In some cases an opening in the wall of the stomach has been successfully closed by sewing over it a graft of omentum, without suturing the opening at all or by pushing a piece of omentum through the opening, just as a cork is pushed into a bottle. If it is found impossible to close the wound in the stomach by any of these plans, then the wound must be surrounded by iodoform gauze, in order to protect the peritoneal cavity from infection; a drainage tube must be carried down to the opening, and a gastric fistula must be deliberately formed. At a later period this fistula will probably heal of itself; but if it does not do so, it can be closed by a plastic operation.

When a surgeon deals with a wound of the stomach, he should always be alive to the possible existence of a wound of the posterior wall; and, in order to determine whether or not such a wound exists, he should tear through the gastrocolic omentum and inspect the posterior wall. If a wound is found in this situation it should be sutured according to the ordinary rules. When there has been a wound of the posterior wall of the stomach the pancreas must be inspected to see if it has been injured, and it is usually advisable to make posterior drainage of the lesser peritoneal cavity.

After the operation of gastrorrhaphy a piece of gauze should be carried down to the suture line, and should be retained for at least twenty-four hours. Such a manœuvre never does any harm; it aids in the formation of adhesions that will eliminate the stomach wound from the peritoneal cavity; and, if leakage does occur, it gives exit to it and thus probably saves the patient's life. I utterly disbelieve in the propriety of closing a wound of the stomach without drainage.

2. *Gastrolysis.*—By this operation we separate or partially extirpate perigastric adhesions. Such adhesions are far more common than was once thought, and are frequently productive of much suffering. They may result from traumatism, from tuberculosis, or from syphilis, but are most commonly due to fibrous thickening about an ulcer of the stomach, or to gall stones or cholangitis.

Such adhesions may attach the stomach to the gall bladder, to the gall ducts, to the omentum, and to other parts. The pain produced by them is particularly appreciated on taking food, and is usually relieved on lying down. They may also cause constriction of one of the orifices of the stomach, and usually induce the condition that Calwell named adhesion dyspepsia. Mayo points out that dilatation is often present, but, unlike what occurs in the dilatation due to ulcer, there are few symptoms of ordinary indigestion.

When such a condition is suspected to exist, we should, after opening the abdomen, follow the advice of Bird (*Inter-Colonial Medical Journal of Australasia*, December 20th, 1900) and inspect first the region of the gall bladder, in which such adhesions are most commonly met with, and then the other neighborhoods in which they may exist. When the adhesion is trivial, is very slender, or is in the form of a narrow band, we can simply separate it; and when this is done, most patients will be cured and practically all will be benefited. When an adhesion is very firm and long, it may be necessary to ligate it at each end and excise it. In separating adhesions the bleeding is generally so slight that ligation is rarely necessary. In severe cases in which the adhesions constrict the pyloric outlet of the stomach, gastro-enterostomy should be performed, the anterior operation being employed for posterior adhesions and the posterior operation for anterior adhesions. Always remember that adhesions may mark the site of an unhealed ulcer, and if they do so the ulcer should be treated surgically.

3. *Gastropexy.*—When the stomach droops the condition is known as gastroptosis; and this may exist alone or in association with the drooping of other abdominal viscera. When the stomach droops it passes into a more or less vertical position. The condition is not at all unusual in women, and its frequency may be estimated from the report of Steele and Francine that, in the Medical Dispensary of the Hospital of the University of Pennsylvania, sixty-three cases of gastroptosis have been recognized during the last two years.

When gastroptosis exists, the supports of the stomach are elongated. These supports are the gastrohepatic omentum and the gastrophrenic ligament. Duret advocates treating such cases by suturing the stomach to the peritoneum of the anterior abdominal wall. In view of the fact that dilatation of the stomach is a frequent secondary consequence of gastroptosis, some surgeons advocate gastro-enterostomy as the proper operation. If the liver likewise droops, it should certainly be lifted back to its place and sutured.

The most promising operation is that devised by Henry D. Beyea (*Pennsylvania Medical Journal*, November, 1902). He describes his operation as follows:

Make an incision three inches long, midway between the ensiform cartilage and the umbilicus. Place three transverse rows of interrupted silk sutures, from above downward and from right to left, through the gastrohepatic omentum, and another series through the gastrophrenic ligament. Tie these sutures, and thus form a broad transverse fold, or plication, in each ligament, that will shorten the ligamentous supports and lift the stomach into its normal position. Beyea says that seven cases have been operated upon, up to the present time, by himself and other operators. Six of these cases have now been observed for from sixty-five days to three years after the operation. In every patient the symptoms have been completely relieved and the health has been remarkably improved.

4. *Gastroplication.*—In this operation we seek to diminish

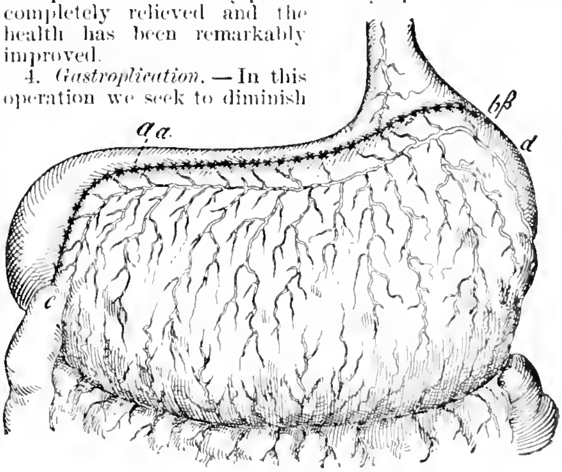

FIG. 4523.—Bircher's Method of Gastroplication. (Keen.)

the size of a dilated stomach by taking tucks in its wall. The term gastrorrhaphy has likewise been employed to designate this operation; but, as before stated, the name gastrorrhaphy should be restricted to the suturing of a wound or a perforation.

Gastroplication has been used to prevent the perforation of an ulcer, but its chief use is in dilated stomach. Clearly, however, when this dilatation is due to pyloric obstruction, such an operation must fail of effect, because it does not remove the cause of the difficulty; therefore when dilatation of the stomach is secondary to pyloric obstruction, that obstruction should be abolished by some of the methods subsequently to be considered, or gastro-enterostomy should be performed. The operation of gastroplication, if employed at all, should be restricted to cases of dilatation due purely to muscular atony, in which the digestive powers are at a low ebb because of the atony.

Different methods have been employed. One is to turn the greater curvature upward upon the lesser curvature and suture the two together (Fig. 4523). Two broad and lengthy layers of the anterior wall may be sutured together, or a very great number of small areas may be approximated by inversion sutures. Brandt, for instance, employed over two hundred sutures in one case.

The value of this operation is very questionable; and we lean to the view of Wölfler that, as the causative condition, whatever it may be, remains untouched, the dilatation will probably be reproduced.

5. *Gastrotomy.*—Gastrotomy means the making of an incision into the stomach and closing the incision at the termination of the operation. Gastrotomy is employed for exploration, for the removal of a foreign body from the stomach, for the arrest of hemorrhage, to permit of the dilatation of a stricture of the œsophagus or of a stricture of the pylorus, or to facilitate the removal of a foreign body from the œsophagus. This operation was performed now and then even in ancient times. In 1532 Matthias, of Brandenburg, successfully removed a knife from the interior of the stomach. The stomach is opened in the following manner:

The abdominal incision is usually made in the median line above the umbilicus. If we are operating for a foreign body in the stomach, when the organ is exposed the foreign body should be located by palpation; and if the body is sharp, every precaution should be taken to prevent injury during the manipulation. Jacobson gives us the sound advice that in dealing with a sharp body with one blunt end, the blunt end should be located first.

The portion of the stomach to be incised is then brought out of the wound and surrounded with gauze. An incision transverse to the long axis is now made, preferably with scissors. Any bleeding vessels are caught with forceps, the foreign body is removed, mucus and blood are eliminated from the interior of the viscus by gentle sponging, its wall is inspected to see that it has not been seriously damaged, bleeding vessels are ligated, the stomach wound is sutured in accordance with the directions given under the heading of gastrorrhaphy, the stomach is restored to its proper position, a small piece of gauze is carried down to the stitch line for drainage, and the abdominal wound is closed.

If operating for the arrest of hemorrhage from the stomach, after the anterior wall has been incised the interior of the stomach is explored with an electric-lighted endoscopic tube and the bleeding point is located. If it is in the anterior wall, it is treated through this incision. If it is in the posterior wall, an opening is torn through the gastrocolic omentum; a finger is passed up into the lesser peritoneal cavity, and the portion of the posterior wall at which the bleeding point is located is inverted with the finger, so that it may be readily recognized through the anterior incision. Then the vessel is ligated or sutured, as the surgeon may elect. After ligating a bleeding point or suturing it with a portion of the stom-

ach wall, apply several inversion sutures to the overlying part of the stomach surface. The operation as employed for the removal of a foreign body in the œsophagus is described in the section on the œsophagus.

The operation of gastrotomy is the antecedent to the performance of Abbe's string-saw operation for stricture of the œsophagus—a procedure that will be found described under the heading "Cicatricial Stricture, etc.," on page 477. The operation of gastrotomy is likewise a necessary antecedent to the performance of Loreta's operation of digital divulsion of a stricture of the pylorus. If gastrotomy has been employed for the arrest of hemorrhage, it should usually be associated with gastroenterostomy, which latter operation will put the stomach at rest after the hemorrhage has been checked.

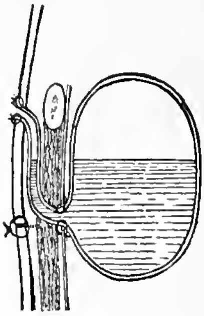

FIG. 4525.—Section to show the Line of the Stomach Wall after the Performance of Gastrostomy by the Ssabanejew-Franck Method. (Meyer.)

6. *Gastrostomy.* — Gastrostomy means the making of a permanent opening into the stomach. This opening is used for the introduction of food. The operation was first performed by Sedillot in 1849. It is usually employed in cases of malignant stricture of the œsophagus, is occasionally used in cases of very marked fibrous stricture of the œsophagus, and has been employed on persons suffering from obstructing cancer of the pharynx, on the victims of œsophageal diverticula, and on individuals who have swallowed corrosive liquids and to whom swallowing is difficult or impossible and in whom stricture is certain to arise. At the present time it would scarcely be used in œsophageal diverticula. In only one instance have I ever employed the operation for anything except malignant disease. That case was one of fibrous stricture of the œsophagus associated with great spasm. The stomach was opened with the intention of distending the stricture from below, or of cutting it by the Abbe string-saw method. This was, however, found to be impossible; therefore the operation of gastrostomy was performed. The results in this case were remarkable. In a few weeks it became possible to pass bougies from above; and subsequently, when the stricture was well dilated, the gastrostomy opening was allowed to close. In such a case as the above, gastrostomy is of benefit, not only by enabling the patient to take sufficient food to maintain his strength, but also by giving complete rest to the strictured area and thus relieving spasm and promoting the absorption of inflammatory exudate.

The operation of gastrostomy has been condemned by many surgeons on the ground that it is extremely fatal; and, as a matter of fact, when performed late in a case of malignant disease, it is very fatal. At this late period the patient is already exhausted, the shock of the operation may be profound, the wound heals badly, and the patient's tissue resistance is at such a low ebb that infection is quite likely to occur. Gastrostomy should not be reserved for cases *in extremis.* When a man is nearly dead, the operation is almost sure to be fatal; and even if passed through successfully, it will prolong the sufferer's life for but a short time. It ought to be performed much earlier, or not at all. As J. B. Murphy says, gastrostomy has no place as a last resort and should only be used in cases without pronounced constitutional symptoms (Chicago *Medical Recorder*, June 15th, 1902). When done at an earlier period, it gives the greatest possible ease and comfort, and may prolong the life of a cancer patient for weeks or months. Mikulicz's rule appeals to us as being a sound one; *i.e.*, when the patient shows a progressive loss of weight and when he begins to develop difficulty in swallowing semisolids and liquids, then the operation should be performed. Then it can be done with the greatest safety, and then it will give the greatest relief and the greatest prolongation of life. When the operation is done at this time, it usually relieves the patient of much distress and uneasiness; it enables him to take plenty of food, thus counteracting weakness and depression; and, in fact, after an early gastrostomy there is, as a rule, a very distinct gain in weight.

When cases are operated upon early it is usually safe to give a general anæsthetic; but when the case is at all advanced or when the patient is weak, a local anæsthetic should be used. I have done the operation with ease and safety under local anæsthesia; in fact, when the hæmoglobin of the blood is distinctly below fifty per cent., I always elect to do it under local anæsthesia.

In performing this operation the surgeon must so do it as to prevent subsequent leakage of the gastric contents. If the fistula leaks, the fluid, as it flows over the surface, will produce irritation and inflammation of the skin and harassing annoyance to the patient. When gastrostomy was performed according to the old methods, leakage inevitably happened. By all of these old methods the stomach was fixed to the abdominal wall and opened a few days later. A large opening was made; the fistula thus formed enlarged, rather than contracted, and leakage took place.

Modern operations are much more satisfactory. The operation that is the most satisfactory in the majority of cases is the one known as the Ssabanejew-Franck method. Ssabanejew devised this operation in the year 1890; and some three years later Franck practised the same method, without being aware of his predecessor's labors. In order to perform this operation an incision is made at the border of the left ribs, and a cone of the stomach is drawn out through this incision. This cone should be at least an inch and a half in length. About an inch above the rib borders a second incision is made through the skin, and the bridge of skin between the two cuts is undermined with a blunt instrument. The base of the stomach cone is sutured to the parietal peritoneum, and the apex is caught with forceps, pulled under the undermined skin, made to emerge through the second opening above the border of the ribs, and sutured there. The incision in the abdomen is then closed. The apex of the cone may be opened at once; and whenever it is desired to feed the patient, a tube may be introduced. This fistula does not leak; it has no tendency to contract, and it is not necessary to wear a tube permanently. It is an admirable operation; it can be very easily and quickly performed; there is no danger of sepsis from the escape of the contents of the stomach, and no buried sutures are employed. It is not, however, applicable to all cases. When the stomach is shrunken and contracted, or when it is very adherent at some portion, one will not be able to pull out a cone an inch and a half long; and if a cone of this length cannot be obtained, one should not do the operation. In two cases I have taken the cone beneath the muscles, as well as beneath the skin; but I question the necessity of this modification.

A. W. Mayo Robson declares himself eminently satisfied with Franck's operation. He, however, employs it in a

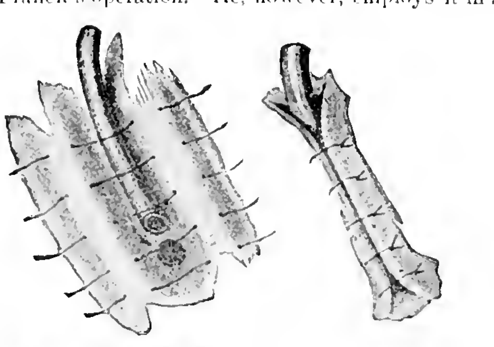

FIG. 4526.—Witzel's Gastrostomy. (Esmarch and Kowalzig.)

somewhat modified form. He makes a vertical incision, an inch and a half in length, over the outer third of the left rectus muscle. This incision commences three-quarters of an inch below the costal margin. He then separates the fibres of the rectus, by blunt dissection, to the same extent as the external incision, and afterward divides the posterior portion of the rectus sheath and the peritoneum by an incision an inch in length. He brings a cone from the cardiac end of the stomach up through the wound, and has it held upward by an assistant while the base of the cone is sutured to the parietal peritoneum. He next makes a transverse incision, half an inch in length, through the skin, one inch above the upper end of the

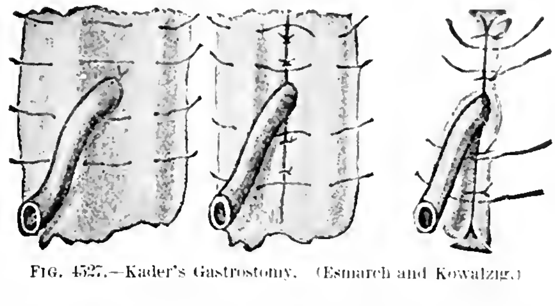

FIG. 4527.—Kader's Gastrostomy. (Esmarch and Kowalzig.)

first incision; undermines the skin between the two openings; introduces a pair of forceps through the upper incision; catches the cone of stomach, and draws it to and a little beyond the second opening, where it is retained between two harelip pins. This portion of the cone completely fills the second opening, and no stitches are necessary. The lower opening is then sutured.

Unless early opening of the stomach is necessary, the surgeon should wait twenty-four hours, in order that a protective barrier of lymph may be thrown out. When the stomach is opened it is done by passing a tenotome between the pins. After the opening is made, a soft-rubber catheter—from No. 8 to No. 12—is inserted, and is retained for a few days. When it is desired to feed the patient a funnel is attached to the catheter. After a few days the catheter is removed, and is then introduced temporarily whenever food is required.

In Witzel's method of gastrostomy (Fig. 4526) a cone of the stomach wall protrudes into the lumen of this viscus, and leaking is thus antagonized. The operation is performed as follows:

The preferable incision is a vertical one through the rectus muscle of the left side. The cardiac end of the stomach is exposed and drawn out, and a very small opening is made, into which a rubber tube about the size of a lead-pencil is introduced. A part of this tube, where it lies upon the wall of the stomach, is buried in the stomach wall by stitching two folds of this wall over the tube with Lembert sutures. The free end of the tube emerges from the wound, and the surface of the stomach about the tube is sutured to the parietal peritoneum. The abdominal wound is then closed. The end of the external portion of the tube is now clamped and the dressings are applied. Food may be administered immediately after the operation, if it is desirable.

I do not like this method as well as Franck's operation. In the first place, it is necessary to use intra-abdominal sutures. There is also some danger of leakage; and the fact that the tube crosses the surface of the stomach may, as it did in one case, cause the formation of an hour-glass constriction.

Kader's operation is employed when, because of the small size of the stomach or of adhesions of this viscus, it is impossible to obtain a sufficiently large cone to perform the Franck operation. I have used Kader's method with great satisfaction. It may be regarded as a modification of Witzel's operation, and is performed as follows:

A three-inch incision is made two fingers' breadths below and parallel with the border of the left lower ribs; or, which is preferable, a vertical incision is made through the left rectus muscle. A fold of the wall of the stomach is drawn forward; a small incision is made, as in Witzel's operation; and the tube is pushed into the stomach for a distance of two inches (Fig. 4527). This tube is then fastened to the stomach wall with a single catgut suture; and a Lembert suture is placed on each side of the tube, each suture raising and uniting a fold about half an inch in width and making a groove about three quarters of an inch in width. When the sutures are tied, longitudinal folds are formed. A portion of the stomach wall is turned inward and surrounds the tube. Over this first fold other folds are made, usually two in number. Then the stomach is stitched to the parietal peritoneum and to the posterior portion of the rectus sheath. The abdominal wound is closed, the other end of the tube emerging from it. In cases in which the stomach is very much contracted it may be necessary to open the viscus within the abdomen, because it will be found impossible to pull it up sufficiently to open it extraperitoneally.

The operation of the younger Senn, of Chicago, is advocated by a number of surgeons. He, too, makes a valve of the stomach wall; and the opening thus formed does not leak during the digestion of food, and may be opened by the passage of a tube when we wish to administer food.

I regard the Franck operation as the easiest, safest, and most satisfactory when it can be performed; when it cannot, I prefer the method of Kader.

7. *Gastro-enterostomy.*—Gastro-enterostomy is the operation of making an anastomosis between a portion of the small intestine and the stomach. It was first suggested in 1881 by Nicoladoni, and was first performed by Wölfler, in the same year (Fig. 4528). The anastomosis may be, and usually is, made between the stomach and the jejunum, and then the correct name of the procedure is gastrojejunostomy. It may, however, be made between the stomach and the duodenum, and is then known as gastroduodenostomy. We shall consider particularly gastrojejunostomy.

The operation of *gastrojejunostomy* may be performed when there is pyloric obstruction, malignant or non-malignant in character; when there is ulceration of the stomach, especially if associated with hemorrhage; when perigastric adhesions produce adhesion dyspepsia; when there is dilatation of the stomach from any cause; when there is grave indigestion that is unamended by ordinary means; and when there is congenital hypertrophy of the pylorus. In dilatation due to simple muscular atony, the operation, as we have previously stated, is of no value. When dilatation and hypertrophy are associated with spasm of the pylorus, the operation is not indicated. Its employment in uncorrectable indigestions has been suggested by Hartmann and warmly advocated by Keen. When the surgeon is dealing with cancer of the pylorus he must choose between pylorectomy and gastro enterostomy. When he is dealing with non-malignant stricture of the pylorus, he must frequently choose between pyloroplasty and gastro-enterostomy. In a case of non-malignant stricture of the pylorus, if the pylorus is accessible and if the plastic operation is possible, we should prefer pyloroplasty, as it keeps the parts in a natural condition and saves the patient from some not improbable post-operative complication.

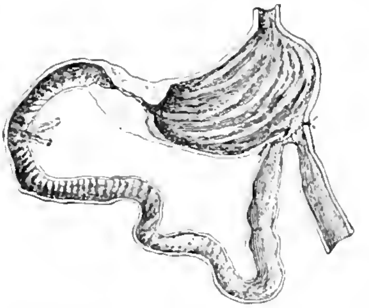

FIG. 4528. Wölfler's First Method of Gastro-enterostomy. (Esmarch and Kowalzig.)

In cancer, if the adhesions are not too extensive, if the growth is not disseminated into near by or distant viscera, and if it is found possible to remove the associated lymphatic glands, pylorectomy is usually performed in preference to gastro-enterostomy; in fact, we may say that in early cases of cancer of the pylorus pylorectomy is to be preferred, and that in very advanced cases gastro enterostomy is of no use. It is rather in the medium type of cases that gastro-enterostomy should be employed; *i.e.*, in persons in whom the growth from the pylorus is irremovable, but who have not yet passed into advanced cachexia and exhaustion.

In a non-malignant case of stricture of the pylorus gastro enterostomy may produce a permanent cure. It frequently relieves the acidity; it enables the stomach to empty itself more rapidly, and thus prevents fermentation and gives rest to the organ. After the operation the motor power of the stomach usually increases, the secretory power often improves, and some stomach digestion usually occurs. As a rule, a certain amount of bile flows into the stomach after the performance of gastro-enterostomy. This was noted in most of Weir's cases. It seems, however, to do no particular harm unless it is present in quantity, or unless it has difficulty in flowing out again. If hyperacidity exists the operation commonly has the effect of causing a lessening or a disappearance of free hydrochloric acid. Of course, even in non-malignant cases the operation sometimes fails of effect.

One of the most valuable effects produced by gastro-enterostomy in either malignant or non-malignant obstruction is the return of regular bowel movements. The operation is, of course, infinitely more serviceable in non-malignant than in malignant cases. In a malignant case it may be followed by a rapid gain in weight; but this gain is only temporary. If, after the performance of gastro-enterostomy, there be marked and prolonged gain in weight, we should be justified in concluding that the disease was not cancer.

The mortality of the operation has been regarded as very high; but when we analyze the figures, we find that it is very high in malignant and not very high in non-malignant cases. In cases of malignant disease the mortality is frequently in the neighborhood of forty per cent.; even in the hands of Mikulicz it has been thirty-two per cent. The Mayos (William and Charles) report ninety-eight gastro-enterostomies with nine deaths, the mortality in malignant cases having been twenty per cent. and in non-malignant cases six per cent. This high mortality in malignant disease is due to the fact that the operation is frequently done too late, when the patient is exhausted and near to death. It should not be done on cases *in extremis*, and, as before stated, should be employed when the case is too far advanced for pylorectomy, but is not very cachectic or much exhausted.

The period of prolongation of life produced by the operation in malignant disease is doubtful. It may be a few weeks, a few months, or a year or more. It is, however, rarely more than a few months. Because of the short prolongation of life and the very high mortality, many surgeons have questioned the value of gastro-enterostomy in malignant disease; but it undoubtedly makes the patient more comfortable. It allays pain; it stops the harassing hunger and torturing thirst; it causes a return of normal bowel movements; and it makes life at least bearable. As Keen says, it is not so much a question of how long a patient lives as how he lives.

In non-malignant cases the mortality is very low. Karle, of Turin, reported twenty-three operations without a single death; and Karle and Fantine estimate that the mortality from operations in non-malignant cases is under four per cent. In such cases the operation is often positively curative; and in nearly all cases it will, at least, give definite and prolonged relief.

There is a fundamental difference in methods of performing this operation, in the fact that the anastomosis may be made upon the anterior wall of the stomach or upon the posterior wall (Figs. 4531–4536). Each method has its advocates. The anterior operation may be performed more readily and quickly; and its advocates maintain that, if it is properly performed, it is safer and more satisfactory than the posterior. In some cases the anterior operation must be performed because the posterior wall cannot be reached. The advocates of the posterior operation maintain that the anterior operation is more liable to be followed by a vicious circle; that the cone of stomach pulled down occasionally compresses the large intestine and produces obstruction; that the posterior operation has very little tendency to be followed by a vicious circle; and that, whereas it takes somewhat longer to do, it is a question whether the mortality is distinctly higher. Further, it is well known that if a button is used in the anterior operation, this mechanical appliance is far more apt to remain in the stomach than if the posterior operation is performed.

Whichever operation is selected, the stomach should be washed out daily for several days preceding its performance. The abdomen should be cleansed at least forty-eight hours before the operation; and during the operation the patient must be carefully protected from cold by being wrapped in blankets and being surrounded with hot-water bottles.

The first incision in the abdominal wall should be small, in order to permit of exploration, so that the surgeon may determine whether gastro-enterostomy is to be performed at all and what method is to be employed. The abdominal incision is then enlarged. If speed is not a vital point in the case, the simple suture without mechanical aid should be selected; if speed is a vital element, one should use a Murphy button, bearing in mind that there is a possibility that this button may be retained. I would do no operation by means of the forceps of La Place or O'Hara, because forceps turn in a very large septum after previously bruising it, and consequently expose a large bruised, raw surface to infection. I am persuaded that operations by means of forceps are more apt than are operations by other methods to be followed by sloughing or by obstruction of the anastomosis opening. Personally, I perform, in most cases, a posterior gastro-enterostomy, effected by a simple suture if the patient's condition is good, and by a Murphy button if haste is imperatively necessary.

A great many operations have been devised, but only a few of the most valuable will be mentioned here.

After-effects of Gastro-enterostomy.—The effects of this operation upon the motor power, the secretory function, and the digestive capacity of the stomach have been referred to previously. Certain pernicious conditions may also ensue; for instance, in a few cases ulcer has formed in the intestine, being apparently due to the extreme acidity of the gastric juice. Neumann suggests that this complication may be cured by making a temporary fistula, and keeping it open until the excessive acidity of the gastric juice has disappeared.

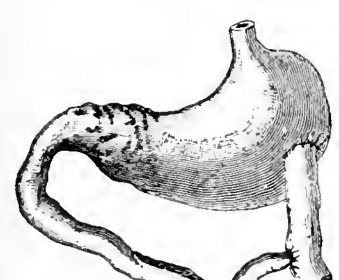

FIG. 4529.—Wölfler's second Method of Gastro-enterostomy. (Esmarch and Kowalzig.)

The most common ill-consequences of gastro-enterostomy are constriction of the new opening, and vomiting, due to regurgitation from the duodenum or to the establishment of what is known as a vicious circle. In every case the new opening contracts to some extent, and occasionally it absolutely closes. The lesson to be drawn from this is that the opening made should be of considerable size. When the stomach is very much dilated at the time of operation, the contraction of the opening is sure to be notable as the viscus shrinks; hence the greater the dilatation, the larger should be the opening. Contraction of the opening is indicated by burning pain, nausea, and it may be regurgitation of small quantities of bile (Mayo).

In some patients, after gastro-enterostomy the fluid from the stomach passes into the proximal loop of intestine and distends it, and the distal loop undergoes collapse. The collection of fluid in the proximal loop may be due to the retention of the secretions that normally enter into that loop, with the addition, it may be, of the passage of a certain amount of material from the stomach through the strictured pylorus. Such a condition may be brought about by the abolition of peristaltic movement in the proximal loop; by the constriction of the distal loop, through an adhesion, a twist, or a kink; or by the formation of a spur, which prevents the passage of material from the proximal into the distal loop.

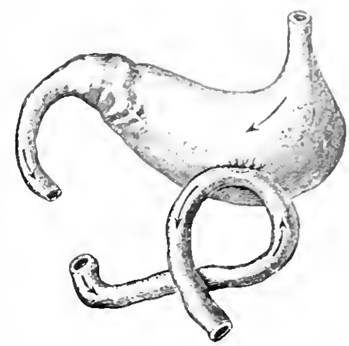

FIG. 4530.—Lücke's Method of Gastro-enterostomy. (Esmarch and Kowalzig.)

The term vicious circle means that the contents of the stomach enter into the duodenal loop and are then returned to the stomach, with bile, pancreatic juice, and other contents of the duodenum. George Ryerson Fowler (*Annals of Surgery*, November, 1902) opposes the use of the term vicious circle, and prefers to say regurgitation, or, better still, reflux, when he wishes to indicate the passage of bile and pancreatic secretion, as well as that of the contents of the jejunum, into the stomach. As previously stated, after every operation of this sort some bile enters into the stomach; but if only a small amount enters, it produces no harm, and the condition will practically amend itself; and even if a considerable quantity enters the stomach it causes little trouble if it readily passes from the stomach into the distal loop. Sometimes there is slight and temporary vomiting, which after a time passes away. At other times the vomiting is extremely serious, and may even hurry the patient to death. Because the vomited matter seemed to be chiefly composed of bile, the trouble has been attributed purely to the presence of bile; but A. W. Mayo Robson maintains that the presence of bile alone is not sufficient cause for the vomiting, and neither is the presence of pancreatic juice. He says that the real cause of the vomiting is not definitely understood. If this vomiting is trivial, it may often be controlled by frequently washing out the stomach and by temporarily abandoning mouth-feeding; but if the vomiting is severe, it is usually met by performing an additional anastomosis between the portion of the duodenal loop above the anastomotic opening and a portion of the jejunal loop below this opening. In the older operations of gastro-enterostomy, the contents of the duodenum inevitably passed into the stomach through the anastomotic opening. They then mixed with the other stomach contents and entered the distal loop. In the perfecting of the modern operations of gastro-enterostomy, the constant effort has been to avoid this complication; for instance, Wölfler, in his second method, cut the jejunum across, implanted the end in the stomach, and fixed the end of the duodenal portion into the efferent portion (Fig. 4529). Lücke so arranged the loop for anastomosis that the peristaltic wave would be in the same direction in the stomach and in the distal portion of the loop (Fig. 4530). The following methods will be described: anterior gastro-enterostomy as practised by Mayo, of Rochester, Minn.; and von Hacker's method of posterior gastro-enterostomy.

In regard to the use of simple sutures or of some mechanical appliance, each operation must be considered on its own merits. The operation with the Murphy button can be done in about fifteen minutes. The surgeon should be certain that the two halves of the button are tightly forced together, and supplementary sutures will then not be necessary. The button may pass during the second week, but rarely does so until the third. In one of my cases of posterior gastro-enterostomy it did not pass until the ninetieth day. Sometimes it does not pass at all, and this complication is said to be particularly apt to occur after anterior gastro-enterostomy; although, strange to say, the retention of the button seems rarely to produce harm. The opening made by the button is sometimes scarcely large enough, and is particularly apt to contract to an unfortunately small size if the stomach is very much dilated. In using the button, we may employ the purse-string suture around the central tube, as Murphy does, or follow the plan of Karle, which is to make a small incision, insert the button, and put a small stitch on each side of the central tube, thus saving time and handling. I do not believe that the button operation is desirable if the anterior gastro-enterostomy is employed. Mayo Robson advocates the use of a bone bobbin. If the anterior operation is employed, I believe that simple suturing is desirable or that Robson's bone bobbin should be used.

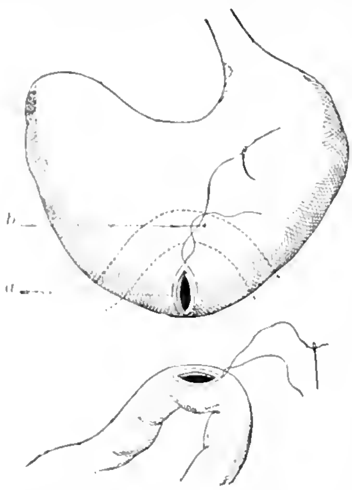

FIG. 4531. Showing Proper and Improper Locations of the Opening in Gastro-enterostomy. (From Dr. William J. Mayo, in *Annals of Surgery*, August, 1902.) *a*, Proper position, which leaves no pouch; *b*, usual position, which leads to the formation of an intragastric pouch.

Anterior Gastro-enterostomy.—Mayo says that the anterior method has certain distinct advantages. It does not open the lesser peritoneal cavity, as does the posterior operation; it can be done with a smaller incision and less exposure; and, hence, it is safer and simpler. Mayo prefers it to the posterior, and says that a careful examination of literature does not show the frequency of the ill-effects so often attributed to it. As a matter of fact, the reports of the Breslau Clinic show the best results from the anterior operation. Mayo employs the anterior operation if the mesentery is short or contains much fat, or if the vascular loop running to the transverse colon from the superior mesenteric artery is small, "bringing the opening in the posterior layer of the gastrocolic omentum in close proximity to it" (*Annals of Surgery*, August, 1902). Some operators maintain that as the stomach shrinks the transverse colon will be pressed upon or constricted, but this will not happen if there is plenty of slack. That regurgitant vomiting is not common even after the anterior operation is shown by the fact that Czerny had but one fatal case out of sixty-five operations. Mayo had two cases of vomiting in thirty-one gastro-enterostomies, each case having been controlled by lavage. In twenty non-malignant cases he did not have a single instance of vomiting.

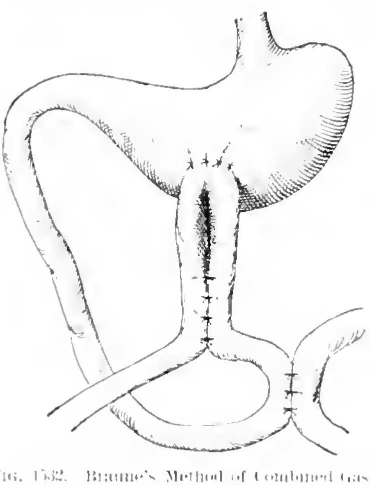

FIG. 4532. Braune's Method of Combined Gastro-enterostomy and Entero-enterostomy.

The operation should be done without a button, if the condition of the patient is good; with a button, if haste is necessary. The button is probably more apt to be retained in the anterior than in the posterior operation.

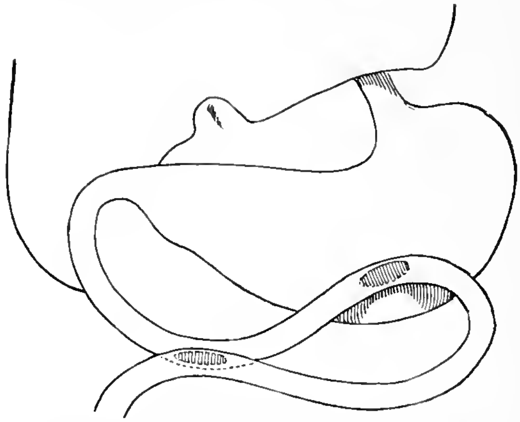

FIG. 4533. Jaboulay's Method of Combined Gastro-enterostomy and Entero-enterostomy.

A portion of the anterior wall of the stomach toward the pylorus is selected. Mayo tells us not to go too near the pylorus, because to do so means early invasion by cancer. The opening must be as near the pylorus as it is safe to go without the apprehension of involvement. Mayo's rule is, place the opening near the greater curvature, one inch above the inferior border. When it is so placed, traction will draw down the stomach so that the anterior surface becomes the inferior. The opening will be at the most dependent portion of the stomach pouch, the stomach will empty itself readily, gravity will prevent the entrance of bile, and a vicious circle will not be established (Fig. 4531).

The origin of the jejunum is next sought for, and a coil about fourteen inches in length is obtained. This is so attached to the stomach that peristalsis in the coil and peristalsis in the stomach run in the same direction. If the button is used, it is applied as in an ordinary in-

testinal anastomosis; if simple suturing is employed, it is done as Halsted directs.

Weir is a believer in the plan of Braune and Jaboulay, *i.e.*, the performing of entero-anastomosis, as well as gastro-enterostomy. He performs anastomosis, by means of a Murphy button, between the efferent and the afferent coils. Rutkowski associates a temporary gastrostomy with gastro-enterostomy, carrying a small tube from the stomach incision well into the jejunum. The gastric juice at once passes from the stomach, alongside of the

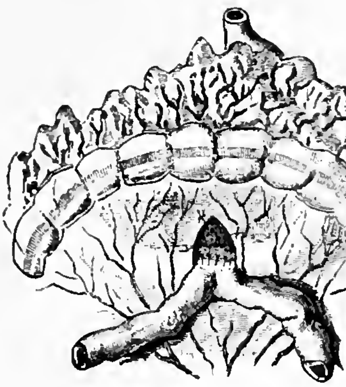

FIG. 4537.—Von Hacker's Method of Posterior Gastro-enterostomy. (Esmarch and Kowalzig.)

tube, into the bowel; and the patient can be fed without danger. Ten days after the operation the gastrostomy wound is allowed to heal.

Posterior Gastro-enterostomy (von Hacker's Operation).—This operation was first devised by von Hacker. It is the preferable operation when the posterior wall of the stomach can be readily reached. Mayo prefers the posterior method for a thin subject with a long mesocolon.

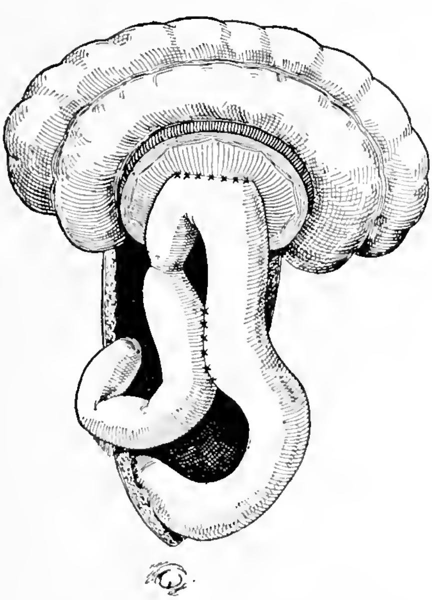

FIG. 4538.—Gastro-enterostomy; Method of Dr. George Ryerson Fowler. (*Annals of Surgery*, November, 1902.)

The bowel is attached to the part of the stomach that is the most dependent when the patient is recumbent. There is less probability of regurgitation of bile than in the anterior operation, and there is a ready passage of food. The bowel is not apt to kink, and if a button is used it is more certain to be passed.

In this operation the great omentum and the transverse colon are lifted upward, a small opening is torn through the transverse mesocolon, and the posterior wall of the stomach is thus reached. A cone of the stomach should be sutured to the margins of the opening in the transverse mesocolon (Fig. 4537). The point in the jejunum at which the anastomosis opening is to be situated is about twelve inches from the beginning of the jejunum. If we have plenty of time the simple suture is used to effect the union; but if it is necessary to has-

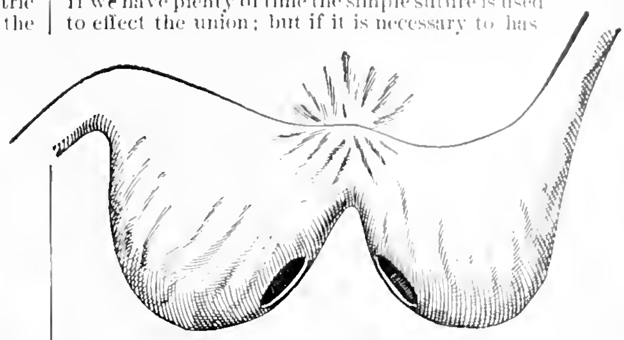

FIG. 4539.—Wölfler's Method of Gastro-gastrostomy for Hour-glass Stomach. (Keen.)

ten, we should use the Murphy button. If the button is used, it is not necessary to stitch the stomach to the opening in the transverse mesocolon. George Ryerson Fowler associates posterior gastro-enterostomy with entero-anastomosis, and cuts off absolutely communication between the stomach and afferent loop by circumclusion

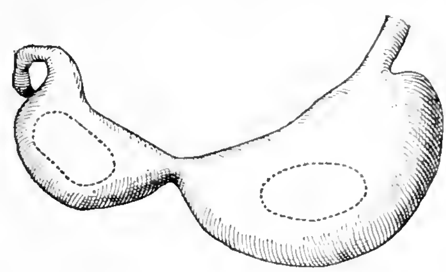

FIG. 4540.—Watson's Method of Gastro-gastrostomy.

of the afferent limb of the jejunum between the anastomotic openings by a silver-wire ligature (*Annals of Surgery*, November, 1902). (Fig. 4538.)

An ingenious method of gastro-enterostomy is that by the elastic ligature. It was devised by Dr. Theodore A. McGraw and has been practised successfully by him and by others. Dr. McGraw says that this method "is unequalled in the rapidity of its execution, its efficiency, and its safety, although it does not accomplish its pur-

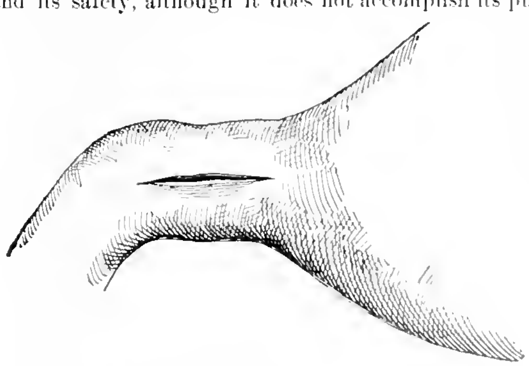

FIG. 4541.—The Heineke-Mikulicz Method of Pyloroplasty. The longitudinal incision. (Keen.)

pose until after the lapse of two or three days" (*New York Medical Journal*, January 26th, 1901). The material used is rubber cord 2 mm. in diameter. One end is shaved thin and passed through the eye of a worsted needle. The intestine and the stomach wall are brought in contact and are sewed together by a number of Lembert sutures in a line. The needle carrying the rubber cord is carried into the stomach and brought out again, the space included being about 5 or 6 cm. in length. It is then entered into the intestine and brought out in a like manner, and the ends are tied "tightly and firmly in a square knot." The ends of the ligature are cut short and are tied together with silk. Lembert sutures are inserted above.

In this operation the ligature cuts through in two or three days, and when it cuts through tissues which are adherent, infection is prevented, and the cord passes away.

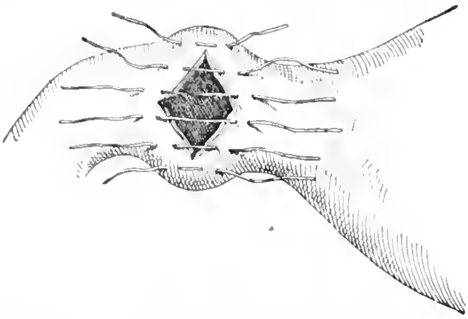

FIG. 4542. The Heineke-Mikulicz Method of Pyloroplasty. Incision stretched at a right angle to its axis and sutures inserted. (Keen.)

Gastroduodenostomy.—This operation has been strongly advocated by some operators; notably Jaboulay and Mikulicz. The pyloric end of the stomach is anastomosed to the anterior portion of the duodenum. In order to perform the operation successfully, the duodenum must be movable. Of course it is never suited to malignant disease, and cannot be performed when the pylorus is adherent. The great advantage of the operation is that the anastomotic opening is above the bile and pancreatic ducts, and hence regurgitation does not occur.

8. *Gastroplasty and Gastro-gastrostomy.*—The condition known as hour-glass stomach may be relieved by the performance of Watson's gastro-gastrostomy (*i.e.*, the anastomosis of the portion of the stomach on one side of the constriction with the portion of the stomach on the other side of the constriction); or of Watson's gastro-gastrostomy; or by gastroplasty (the making of a longitudinal incision through the constricted portion, followed by traction upon the sides of this incision, so that it becomes transverse; and the application of sutures so as to maintain it in this transverse or vertical position). The constriction is thus diminished or abolished. Gastroplasty is the preferable method.

9. *Pyloroplasty* (the Heineke-Mikulicz Operation).—For cicatricial stricture of the pylorus, the older method of Loreta has been practically abandoned, because after

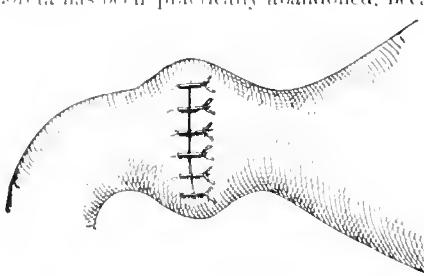

FIG. 4543. The Heineke-Mikulicz Method of Pyloroplasty. Sutures tied and lumen of pylorus inserted. (Keen.)

its performance recurrence is almost inevitable. In such a case, if gastro-enterostomy is not advisable, we perform pyloroplasty—*i.e.*, the surgeon makes a longitudinal incision through the constriction, holds the edges apart to make the line of incision appear vertical, and so applies his stitches as to maintain the vertical direction of the suture line. Thus the constriction is either mitigated or abolished. Mayo points out that pyloroplasty may fail because the degenerated gastric muscle cannot lift the food from the gastric pouches to the high pylorus. If it does fail, do gastro-enterostomy.

10. *Pylorectomy.*—This is the operation of excising the pylorus with a portion of the pyloric end of the stomach. Its performance is practically restricted to malignant disease. The operation was first performed by Péan in 1879.

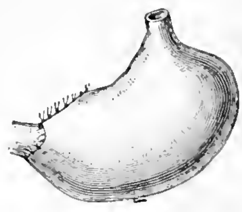

FIG. 4544.—Billroth's Method of Pylorectomy.

The mortality of the operation is extremely great, but has been considerably reduced in recent years. One reason of the high mortality is that many cases have been operated upon too late, when advanced cachexia or wide diffusion of the growth was present. The later we operate and the more marked the adhesions, the heavier the mortality. Wölfler says that the mortality in cases with extensive adhesions is over seventy two per cent., and that in cases without extensive adhesions it is under twenty-eight per cent. Mayo's mortality is only fourteen per cent.

It is rarely that genuine cures are effected by the operation in proved cases of cancer, and it is only when the procedure is undertaken early that there is any real chance of cure. Nevertheless there are more than forty cases in literature which survived three years or more. To give a real chance of cure, the operator must cut wide of the growth on the stomach side. As a matter of fact, the growth usually returns.

As a rule, the abdomen is not opened until a tumor can be palpated, and then it is generally too late for pylorectomy. This fact emphasizes the enormous importance of an exploratory incision in doubtful stomach cases. As making such exploratory incisions becomes more and more the practice, pylorectomy will become more and more successful; because it will be performed earlier. Pylorectomy is a proper operation if the pylorus is not firmly anchored by adhesions, if there is no dissemination into adjacent organs and structures, if

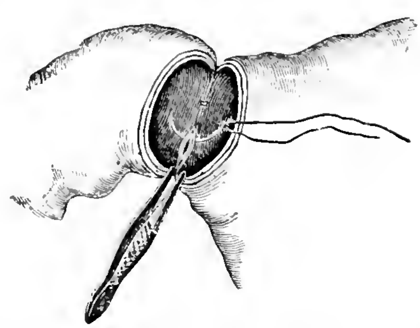

FIG. 4545. Suture of Mucous Membrane from within after Pylorectomy. (Tillmanns.)

there are no distant metastases, and if the affected lymph glands are removable; otherwise, gastro-enterostomy should be done.

The older method of Billroth gave a mortality of from thirty eight to forty per cent., as a rule. In this method, after the resection of the tumor has been accomplished, it is found that the wound in the stomach is larger than that in the duodenum; the stomach wound must therefore be lessened by suturing, until it is practically of the same size as the duodenal wound, when an end-to-end anastomosis is performed.

Kocher's method has been much more successful, and is said by Mayo to give a mortality of only sixteen per cent. In this method, after the tumor has been removed, the stomach end of the cut is completely closed, and the duodenum is implanted in the posterior portion of the stomach wall. Mayo follows Kocher's method with a slight modification. He tells us that Kocher has performed pylorectomy fifty-seven times, that eleven of the patients were living a considerable time after operation, and that five of them were living a sufficient length of time afterward to be regarded as cured.

11. *Gastrectomy.*—*a.* Partial Gastrectomy.—By partial gastrectomy we mean excision of a portion of the stomach. The operation of pylorectomy really includes a partial gastrectomy. We may remove a small portion of the stomach, a considerable portion, or almost the entire organ. In any of these cases the operation is a partial gastrectomy. The operation may be performed for malignant disease or for ulcer. After the extirpation of a malignant growth or of an ulcer, sutures are inserted in the manner recommended by Halsted.

b. Total Gastrectomy.—This operation was first performed by Connor, of Cincinnati. The first successful operation was performed by Schlatter, of Zurich. The operation has now been performed a number of times. Whenever possible, the duodenum is attached to the œsophagus, and it is a matter of surprise how easily this has often been effected. If it is found to be difficult or impossible to do this, an opening is made in the jejunum, and this portion of the bowel is attached to the œsophagus. This operation should, of course, be attempted only in cases in which practically the whole of the stomach is involved, in which the organ is still movable, in which there is no involvement of adjacent structures or viscera, in which there is no metastasis, in which the lymphatic glands are removable, and in which it is possible to attach the œsophagus either to the duodenum or to the jejunum.

It is remarkable how well digestion is performed in cases in which the whole stomach has been removed; but, of course, during the progress of chronic disease, portions of the intestinal canal gradually take upon themselves the functions of the stomach and really effect digestion for quite a while before the removal of the stomach. It is in very rare cases that this operation is necessary, but it is undoubted that it is occasionally justifiable.

12. *Jejunostomy.*—This procedure is occasionally recommended for malignant disease, when gastro-enterostomy is rendered impossible because of the situation of the growth. The permanent opening in the jejunum is used for the purpose of administering food. Either the jejunum itself, cut across, may be brought into the wound, or a tube may be inserted into the wall of the jejunum, exactly as is done in gastrostomy. The operation is very rarely necessary, but in some cases is to be employed.

Exploratory Laparotomy.—In view of the imperative necessity for early diagnosis, if we would successfully cope with many gastric diseases, and especially if we would hope to cure malignant disease, exploratory laparotomy is frequently indicated. The exploration is made to clear up doubt; and after the condition is ascertained, the incision may be enlarged and a radical or a palliative operation may be performed. The surgeon who never operates until the diagnosis is certain must often delay so long in reaching a conclusion that when he is sure what the matter is, he is equally sure that any operation is entirely useless. Dr. J. B. Murphy strongly endorses the following statement made by MacDonald (*Chicago Medical Recorder*, June 15th, 1902): "In a chronic, progressive gastric trouble that is unamended by careful diet and drug treatment; that is accompanied by loss of gastric motility and diminution in gastric peristalsis; and that is attended with emaciation, in spite of forced feeding—especially if associated with progressive reduction in the hæmoglobin, diminution in the hydrochloric acid of the gastric juice, and moderate leucocytosis—an exploratory operation should certainly be performed." With the foregoing statement I am in hearty accord; and when an exploratory operation is performed in such cases, a cancer will usually be found.

Operation for a suspected malignant growth may disclose an innocent growth, and a condition that would have been destructive to life without operation may be permanently cured. I have recently performed an exploratory operation in a case in which the symptoms indicated cancer, and yet in which it was ascertained during the operation that the whole condition was due to cicatricial obstruction of the pylorus. A complete cure followed the performance of pyloroplasty. In conducting an exploration for disease of the stomach, it is necessary, in some instances, not only to open the abdomen, but also to perform exploratory gastrotomy.

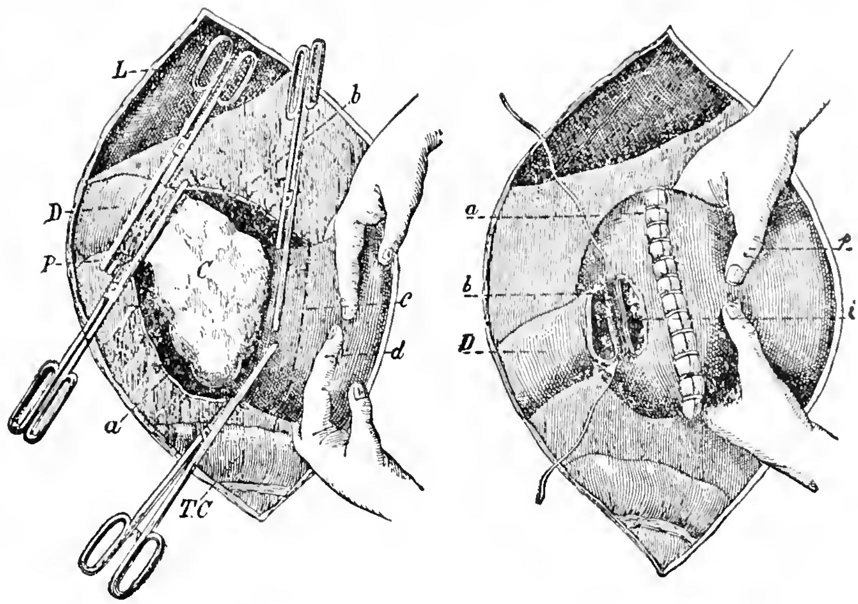

FIG. 4546.—Kocher's Method of Pylorectomy (*A*) and Posterior Gastro-enterostomy (*B*). (Kocher.)

Operations for Ulcer.—It is imperative to remember that the symptoms of perforation are not always certain; hence, when the symptoms that are supposed to indicate perforation are present, an exploratory operation must be immediately performed. When we believe that an ulcer has perforated, the proper means for bringing ing about reaction should be adopted and the abdomen should be opened. There will usually be an escape of odorless gas and fluid, and food will often be found in the peritoneal cavity. The site of the ulcer may sometimes be located by the presence of adhesions, but at other times no adhesions are present, and a very careful search is then necessary.

When the ulcer has been found, it is enough, in most instances, simply to close the perforation with inversion sutures, as described under the head of gastrorrhaphy.

Some surgeons advocate excision of the ulcer as well. When the ulcer's margins are not markedly indurated, and when inversion can be readily effected, it is not worth while to excise. In perforation excision is rarely necessary. In some ulcers which have not perforated and in a few which have, excision is advisable. In a recent case in the Philadelphia Hospital, I was obliged to excise an ulcer which had not perforated. Excision was required because the surrounding induration made marginal inversion impossible. The abdominal cavity is then carefully cleansed, the stomach is washed out, a piece of gauze for drainage is carried down to the stitch line, and the abdominal wound is closed.

In ordinary, non-perforating ulcers, medical and dietetic treatment is indicated in the majority of cases; but if, in spite of such treatment, a patient grows progressively worse, if the pain is violent, or if tenderness is marked, the abdomen should be opened and the stomach should be inspected. A single acute hemorrhage, even if large, does not call for operation; but if the hemorrhage is repeated, operation should be performed. A number of small hemorrhages call for operation. Cabot lays down the sound rule that if an ulcer tends to recur or if it lessens the ability of the patient to work—especially if he must work to live and cannot regulate his diet—an operation should be undertaken.

In operating for chronic ulcer, it is wiser, in most instances, to excise the diseased area, suturing the gap (see Partial Gastrectomy and Gastrorrhaphy). If we are operating for hemorrhage from an ulcer in the anterior wall, the hemorrhage is best controlled by excising the ulcer. In hemorrhage from an ulcer in the posterior wall, the site of trouble is determined by performing exploratory gastrotomy. When the ulcer is located, tear through the gastrocolic omentum, insert a finger back of the stomach, invert the posterior wall, look for the ulcer through a gastrotomy wound in the anterior wall, and arrest the bleeding with a ligature or a suture. After arresting the hemorrhage some advocate the performance of gastro-enterostomy to put the stomach at rest and prevent the retention of acid gastric juice. It has been shown that in cases of ulcer in which it is difficult or impossible to reach the seat of bleeding, gastro-enterostomy alone puts the stomach at rest, permits drainage, and strongly favors cure.

Operations for Cancer.—Exploratory incision should be performed in the cases indicated by Murphy and MacDonald. In limited cancer of the body of the stomach, perform partial gastrectomy and remove adjacent involved glands. In cancer involving the entire stomach, the viscus being movable, adjacent organs being free from disease, no demonstrable metastases existing, and the involved glands being obviously removable, complete gastrectomy is a justifiable operation. Pylorectomy is performed in cancer of the pylorus; but only in cases in which there are no extensive adhesions, no metastases, and no involvement of adjacent viscera, and in which the involved lymph glands are removable. In cancer of the cardiac end of the stomach in which the œsophagus is involved, removal by excision is scarcely justifiable and gastrostomy is practically useless. In some cases jejunostomy should be considered. If a radical operation is impossible in cancer of the body of the stomach, no palliative operation is indicated, except possibly jejunostomy. If a radical operation is impossible in cancer of the pylorus, gastro-enterostomy is performed, or, in rare cases, jejunostomy. *John Chalmers Da Costa.*

STOMACH, DISEASES OF.—Within recent years the literature in gastric diseases has grown so extensively that numerous text-books, good, bad, and indifferent, are now issued. Among the best for the practitioner may be mentioned: Riegel, "Die Erkrankung des Magens," Wien, 1896 (an American edition has just been issued, 1903); Boas, "Diagnostik und Therapie der Magenkrankheiten," Leipzig, 1897; Einhorn, "Diseases of the Stomach," New York, 1900; Hemmeter, J. C., "Diseases of the Stomach," Philadelphia, 1903; Van Valzah and Nisbet, "The Diseases of the Stomach," Philadelphia, 1898; Lindner and Kuttner, "Die Chirurgie des Magens," Berlin, 1898; Martin, S., "Functional and Organic Diseases of the Stomach," London, 1895; Gillespie, "A Manual of Modern Gastric Methods," Edinburgh, 1899; Osler and McCrae, "On Carcinoma of the Stomach," Phila., 1900; L. Brunton et al., in Allbutt's System of Medicine, London, 1897.

In preparing the various sections the writers have drawn freely from some of these authors, where special arrangements and topics have appealed to their requirements.*

I. METHODS OF EXAMINATION IN GASTRIC DISEASE.

Inspection.—This includes both a general examination of the patient and a special investigation of the abdomen in general, and the stomach in particular.

The *general examination* concerns the *nutrition* of the patient, the conditions of the *skin* as to dryness and moisture, the evidences of cachexia, etc. The state of the *teeth*, as one of the common causes of gastric disorder, should be examined and due note made of any condition there which may cause infection—*e.g.*, unnecessary bacterial contamination of food, faulty mastication, etc. Often a false set may fit so badly as to be the sole cause of dyspepsia, induced through insufficient mastication alone. The condition of the *gums* is likewise important. So, too, the state of the *pharynx*, more especially in chronic gastritis, in which the morning vomiting is often due solely to pharyngeal mucus swallowed during the night. Salivation, too, is often associated with disease of the pharynx and of the palate and tonsils.

The state of the *tongue* is very much over-estimated as to its diagnostic significance in gastric disorders. It is the mirror of the mouth much more than of the stomach. There may be a clean tongue in cancer of the stomach, while with merely carious teeth there may be persistent coating. As a rule, however, there is apt to be a clean, reddened tongue with hyperchlorhydria, while with subacidity the tongue is usually coated. A dry tongue is usually associated with mouth-breathing.

Examination of the Abdomen.—*Special inspection* of the stomach and abdomen is useful in not a few diseases, for in them it is possible to tell the size, situation, and even the shape of the stomach. This method is best carried out with the patient lying down, as the erect posture renders the recti abdominis rigid. Normally, nothing of the stomach is to be seen.

Among the abnormal conditions which can often be detected by inspection alone are abnormal distention with gas, gastrectasis (idiopathic or obstructive), stenosis of the pylorus (when the tumor is visible and peristaltic waves are evident), hour-glass constriction, peristaltic unrest (a neurosis), and gastroptosis.

Inspection is aided by *inflation* or *insufflation*. This is carried out by one of two methods:

1. Administration of sodium bicarbonate and tartaric acid in separate solutions, the gas forming in the stomach when the two solutions come into contact.

The details of this method are as follows: According to the age and size of the patient, from half a drachm to one drachm of each is placed in separate tumblers which are then filled to one-third with water. The tartaric acid is first administered, and, before the second tumbler is offered, the patient is directed to retain whatever gas may have formed; then the sodium bicarbonate is administered and the patient is told to lie down. With the body in the horizontal position the inflated stomach rises out of the general level of the abdomen, and a satisfactory inspection of the organ can then be made.

Remarks.—An unsatisfactory result may be due to insufficient dosage, the stomach being more capacious than

* Sections I., II., III., IV., V., VII., VIII., IX., and X. are from the pen of Dr. Charles F. Martin, while the remaining ones (on "Neuroses," "Simple Tumors," "Displacement of the Stomach," and "Foreign Bodies") have been written by Dr. F. Morley Fry.—*Editor.*

anticipated, or to adhesions, or to its situation chiefly in the left hypochondrium or under the ribs, or to incontinence of the pylorus, or, finally, to excessive gastric peristalsis. Or, again, too much gas may be formed and intense pain and unavoidable emesis follow. The physician should have a stomach tube, a basin, and a towel at hand in case the retention of gas give rise to great pain or to sudden uncontrollable emesis.

2. The second method is the introduction of air by means of the stomach tube, the air being propelled by the double-bulbed Higginson's syringe. This has the advantage of controlling the amount of air introduced and the disadvantage incident to passing the stomach tube. This method should never be tried till the patient has used the tube at least once previously, and air should never be introduced in such amount as to cause severe gastric pain. The contraindications to either of these methods are ulcer, recent hæmatemesis, atrophy of the mucous membrane, peritonitis, and advanced cardiac and arterial disease.

Palpation.—Palpation should be performed gently, systematically, with warm hands, the fingers being held flat on the abdomen at first, and the patient recumbent, breathing gently and with knees flexed. Palpation is easier when the stomach is empty, though tumors and the stomach outlines are often felt best after inflation. Narcotization is sometimes necessary to allow of satisfactory palpation, and is indeed to be strongly recommended in doubtful cases. Any tenderness found should be localized definitely and its degree ascertained. Boas' algesimeter has not been found of any great value in diagnosis.

Tumors of the stomach do not move with respiration, as a rule, the stomach being rather broadened out by descent of the diaphragm. Only when they, or the stomach, are adherent to the solid parts which move with respiration can they be made to descend on inspiration, and with expiration they may often be fixed by intervention of the fingers above the tumor.

Succussion.—Succussion implies detection of fluid with air, in a body cavity, by shaking the patient or the portion examined. The patient lies upon his back and relaxes the abdominal muscles. The physician, then grasping the iliac bones and lumbar muscles on both sides, quickly shakes the patient and a splashing sound is heard. Occurring under certain conditions this is distinctive, but may be simulated by fluid in the colon as well. Presence of this sign in the stomach is only pathological when found to extend over an abnormally large area or at times when the stomach is normally empty (*e.g.*, in gastrectasis, five or six hours after a meal), and should not be otherwise regarded as evidence of disease.

It is doubtful if much reliance for the diagnosis of atony can be placed on the following method: Give the patient half a glass of water and try succussion. If this be obtained it arouses suspicion of atony. Therefore try again in half an hour, and, if a positive result is still obtained, then atony is present. If no succussion be present the motor power of the stomach is normal.

In testing for succussion the triangular area of the stomach in contact with the abdominal wall—*i.e.*, the triangle formed by the midline of the abdomen, the left costal border, and a line joining the cartilages of the ninth ribs—should be especially examined.

Percussion.—This evidence varies according to the amount of contents—food or air. The organ is to a large extent inaccessible normally to percussion—only the above-mentioned triangular area and Traube's semilunar space being easily outlined. Percussion may reveal the size, situation, and shape of the organ and the presence of tumors. Increased area may be due to megalogastria, retracted lung or liver, ptosis, weighty tumors, and dilatation. Diminution in the size of the area may result from left pleural or pericardial effusion, pneumothorax, hypertrophied heart, enlarged spleen or left lobe of liver, etc.

Percussion is much assisted by inflation, less so by administration of fluid.

Auscultation and auscultatory percussion have not as yet proved of any great practical value in diagnosis.

Illumination of the stomach by the gastrodiaphane is sometimes valuable in locating its site, but has little other practical use. As a means of demonstrating the abnormal positions of the organ, it is an excellent method if the patient has a thin panniculus.

Examination of the Digestive and Motor Functions of the Stomach.—For this purpose the best means known is by the examination of the gastric contents after administering a test meal of given quantity and quality. This is more satisfactory and reliable than the older method of examining the gastric juice alone after physical, chemical, or electrical stimulation. It is by no means essential in all cases of gastric disorder to employ test meals or the tube; indeed, the tube is used far more frequently than is necessary or even wise. The cases should be selected according to their needs. After a given test meal has been removed we are enabled to decide from the examination to what extent the motor functions are active, and after analyzing the chemical nature of the contents we can tell to what degree the various constituents of the gastric juice are being secreted as aids to digestion.

Three types of test meals are to be recommended:

1. *Test Breakfast:* One piece of dry bread or toast (60 gm.) and a breakfast cup of weak tea (without sugar or milk). This is to be taken slowly, the bread being well masticated and the tea drunk gradually. One hour later this may be removed and examined.

Such a breakfast should have a residue of not more than 75 c.c.; should be of gruel-like consistence; should contain about fifty per cent. total acidity, free hydrochloric acid ten per cent., combined acid forty-five per cent. Such a meal contains albuminoids, sugars, salts, starches, and extractives, and makes no great demand upon the stomach—a point of importance where there is difficulty of digestion. The disadvantage of such a meal is in the fact that it scarcely demands sufficient effort on the part of the secreting glands of this organ.

2. *The Test Lunch of Germain Sée:* A large piece of bread (120 gm.), a cup of water, and 60 gm. of minced meat. This should be removed for examination two hours later. Little more than 200 c.c. will remain from such a meal, and the total acidity will be about sixty per cent. This meal, containing a more varied diet, still further tests the powers of gastric digestion.

3. *Test Dinner of Leube and Riegel:* This consists of a plate of soup (350 c.c.), 60 gm. of scraped beef, and 60 gm. of wheaten bread. In some meals potatoes in purée form and a tumbler of water are added. This meal should be removed four or five hours later, and will contain a still larger amount of hydrochloric acid (total acidity from sixty-five to seventy per cent.), and it will also give the secretory glands a fair test of their functional powers. Another advantage of this meal is that the macroscopical appearances of the contents give at a glance a fair estimate of the way digestion is proceeding, especially as regards the motor power and the digestive power for proteids. Its disadvantages are the risk of clogging of the tube, the long delay after the meal, and the fact that it is often not readily digested.

Method of Removing a Test Meal.—For this purpose an ordinary stomach tube, thirty-six inches (about 90 cm.) long and of different diameters, should be at hand. One should be careful merely to select one of sufficiently large calibre to allow the pharyngeal muscles to grasp it properly, and not so pliable as to bend in the mouth too easily when introduced. The end should be rounded and provided with two velvet eye orifices, and it really matters but little whether these be both lateral or one terminal and the other lateral. With ordinary care there is but little danger of injuring the mucosa of the stomach with the tube end. A bulb attached to the upper end of the tube may be of use in removing the contents by suction; but it is not an essential, as the tube itself may be so pressed and pulled as to create suction and thus withdraw the contents. When it is desired to wash out the stomach a funnel may be substituted for the bulb.

For the operation one requires, in addition, a rubber apron for the patient, two dishes, and a jug of hot water. The patient, seated in an ordinary chair, is then given the tube, which has been previously warmed in water (no other lubricant is necessary), and is directed to swallow it, using his lips to assist in introducing and swallowing the tube. When a gagging sensation supervenes he is instructed to breathe quietly, when he will at once observe the absence of any supposed danger from choking. The head should be held erect, not far backward, and the tongue should not be pressed down. In the case of patients who have a very irritable pharynx, they may be directed, ten minutes beforehand, to suck a pledget of cotton soaked in a five-per cent. solution of cocaine. The introduction of the tube—when such a step becomes necessary—is to be done as follows: With the left index finger as a guide to the back of the pharynx, the tube held in the right hand is quickly passed down over the epiglottis into the gullet and pushed below the level of the cricoid cartilage. The finger is then removed, the patient told to breathe quietly, and then to continue swallowing the tube. The cardia being eighteen inches (45 cm.) from the incisor teeth, twenty-two inches of tube should be inserted before removal of the contents is attempted.

Three methods of removal are employed:

1. *Expression.* This is best achieved by the patient pressing on his stomach, straining as if at stool, and bending forward—the distal end of the tube being meanwhile lowered over a dish to a point below the level of the stomach. Often the act of retching—voluntary or otherwise—aids the process. Any blocking which may seem to occur may be overcome by pressure on the bulb in such a way as to direct the force of air against the stomach end of the tube (*i.e.*, by compressing the tube on the distal end of the bulb). This is better than to remove the tube and to cleanse it, and illustrates one advantage of the bulb.

2. Failure to remove contents in this way must be overcome by *suction*, either by frequent use of the bulb so as to create a vacuum in the tube by directing the current of air outward, or by filling the funnel with water and allowing it to siphon off in the hope that the stomach contents may follow.

3. Should this method also be without result, *complete siphonage* must be tried. This is done by pouring warm water of a known quantity (say one-half pint) into the stomach, as well as retaining water in the whole length of the tube, and thus removing both the water and the contents of the stomach when the siphonage operates. To do this properly one must lower the funnel quickly before all its watery contents reach the stomach, which would otherwise prevent the action of the siphon. Having thus obtained some contents, we can estimate how much of the meal has remained, after deducting the quantity of water poured into the stomach.

Failure to obtain any contents whatsoever may be due to various factors: The motor power may have been abnormally strong and all food may have passed into the duodenum, as occurs in some neuroses. The time may have been too long after the meal. The tube may not have been pushed far enough into the stomach, and thus not have reached the fluid, or it may have been inserted too far, thus allowing the end with its orifices to curl up again above the level of the fluid. The tube may become blocked with food or mucus.

The contents having been successfully obtained, the tube is removed slowly, and, after being half withdrawn, the distal end should be tightly pinched to prevent the dripping of remaining contents; then the stomach end of the tube should be allowed to slip through the other hand and should be grasped firmly just before its complete removal. This insures less mess in removing the tube and allows greater comfort to the patient. The tube is then placed in warm, mildly antiseptic water and cleansed outside and within. It should never be boiled nor curled up after being cleansed.

There is no occasion to resort to other methods recommended (such as the use of the stomach bucket) for the removal of the stomach contents.

The *contraindications* to the use of the tube for diagnosis are as follows: (1) Recent hæmatemesis; (2) peritonitis; (3) pregnancy; (4) disease of heart and arteries, especially aneurism; (5) febrile conditions; (6) great weakness.

Examination of Stomach Contents.—(1) Macroscopical; (2) microscopical; (3) chemical.

Macroscopical.—The *quantity* depends on the kind of meal and the motor power of the stomach. From this alone we can estimate the presence of motor insufficiency of all degrees—the presence of hypermotility and of supersecretion, remembering always that each test meal has its definitely recognized amount of residue; according to the amount left behind so is the degree of motor (not of digestive) power.

Consistence. One should note, further, the relation of solids and liquids. The food may be only partly digested. A good, evenly mixed, soup-like material implies good secretory power or perhaps hyperacidity. The presence of relatively much liquid, as against a small amount of solids, implies one of two conditions: either retention of fluids from motor insufficiency or hypersecretion of gastric juice. Many coarse food particles imply subacidity, while much starchy remains with well-digested meats show hyperacidity. Sometimes the contents on removal separate into *three distinct layers*, the lowest consisting of starches and chyme, the middle one of cloudy fluid, and the uppermost one of foam, on account of gas formation which usually implies stagnation and fermentation of food. With the foam there may also be remnants of undigested food and mucus. The presence of food taken on a previous day implies, of course, retention of food, *i.e.*, an advanced degree of motor insufficiency.

Odor. Normally the contents have what may be termed a gastric odor. One should note the possible evidence of butyric or of acetic acid, both of which acids are best detected in this simple manner. Abnormal fermentation is implied by their presence. According to underlying causes the contents may have a fetid (ulcerating cancers), fecal (obstruction to intestines, etc.), putrid (phlegmonous gastritis, etc.), or urinous (uræmia) odor. Poisons such as hydrocyanic acid, carbolic acid, etc., may each lend their special odors as signs of their having been ingested.

The *specific gravity* of pure gastric juice is 1.002 to 1.005. In hyperacidity the filtered contents have a specific gravity of 1.010 to 1.020. In subacidity this is often still higher, depending partly on the amount of sugar present.

Mucus is readily seen, and normally there is about one-half drachm in a stringy, gelatinous state. It is gray or colorless, and if pigmented we may conclude that it has come from swallowed sputum or from an associated catarrhal condition. Mucus is increased in hyperchlorhydria, in ulcer, in gastritis, and in certain neuroses of the stomach. In hyperchlorhydria the mucus is often in lumps and threads.

Blood from the stomach is bright or dark, according as a large or small vessel is opened, and according to the length of time it has remained in the stomach. It indicates erosion of a vessel, as caused by ulcer, carcinoma, various forms of gastritis and hepatic cirrhosis, strain or trauma, hysteria, etc.

The vomitus, resembling *coffee grounds*, consists of blood and food-remains, the former being dark from its longer sojourn in the stomach and from the action of the gastric juice. Usually it follows an erosion of the smaller and more superficial vessels.

Pus when present is usually associated with phlegmonous gastritis or an ulcerating cancer.

Bile is commonly present, being regurgitated from the duodenum.

Microscopical.—One sees in the contents the food-remains, consisting of striated muscle fibres, starch grains, vegetable cells, fat globules, etc. Abnormally there may be sarcinæ ventriculi, characterized by their brown color and their arrangement in multiples of two (bale shaped); they are usually found with dilatation of the stomach, where hydrochloric acid is present. Yeast cells may be present, as also hosts of bacteria, such as (1) acid forms which do not liquefy gelatin—Bacillus coli, Bacillus lactis aerogenes, etc., and Bacillus butyricus (this does liquefy gelatin); and (2) Bacillus subtilis, Proteus vulgaris, B. fluorescens liquefaciens, Leptothrix, and various micrococci.

The Boas-Oppler bacillus—a thick, long bacillus—is frequently present in advanced motor insufficiency and is commonly found with carcinoma ventriculi, though not an essential feature.

Chemical.—Qualitative Tests. For this purpose the stomach contents should be filtered into a glass beaker, a process which will take time unless the French method of folding the filter paper be adopted. The filtrate is usually clear, slightly yellow, or somewhat opalescent. (Only the most suitable and commendable methods are here given, the various methods being too numerous for the compass of this article.)

The contents are either acid, neutral, or alkaline. If they are neutral or alkaline, one need not go further in testing for acidity; if otherwise, we *first* of all use litmus paper (which is suitable to all free acids, acid salts, and organic acid combinations). If they are acid to litmus, we use, *secondly*, Congo-red paper (a saturated aqueous solution into which white filter paper is steeped), to test for free acids, which if present give to the paper a deep blue. (This is much more sensitive to hydrochloric acid than to the organic acids, while combined acids do not alter the Congo paper.) *Thirdly*, we test for free hydrochloric acid by dimethylamidoazobenzol (one-half-per-cent. alcoholic solution). This yellowish solution is very sensitive to any free mineral acids, and on the addition of a mere trace of free hydrochloric acid a red color appears. Fill one-fourth test tube with the solution, and on addition of a few drops of filtered contents containing free hydrochloric acid the red will appear; 0.002 per cent. of hydrochloric acid will give this reaction. It is the most sensitive reagent as yet known, and though it reacts also to lactic acid and phosphates, it does so only when they are present in concentrated form, which rarely occurs in gastric disease.

Another satisfactory test for free hydrochloric acid must be mentioned, viz., Gunzburg's, whose reagent consists of phloroglucin 2 parts, vanillin 1 part, and absolute alcohol 30 parts. Place on a porcelain dish one drop of this solution, and with it a drop or two of filtered stomach contents. Heat gently over a Bunsen burner, and if free hydrochloric acid be present a rose-red color will appear; a brownish-yellow color is meaningless.

Test for Combined Hydrochloric Acid.—Where free hydrochloric acid is found the combined hydrochloric acid is implied; but should the former be absent, there may still be sufficient acid secreted to fulfil some of the requirements of proteid digestion. This is ascertained by a color test with alizarin (one-per-cent. aqueous solution). Filter the stomach contents, place a few cubic centimetres in two separate test tubes. To one tube add a few drops of alizarin and a decinormal solution of sodium hydrate till a pure violet color appears. Note the amount of NaOH used. To the second tube add the same quantity of one-tenth NaOH, and, if it is found still acid to litmus, combined HCl is present.

The biuret reaction, however, is simpler and shows equally well the presence of combined acids by proving the presence of peptone or propeptone in the filtered contents. Take, therefore, a few cubic centimetres of the stomach contents in a tube, add to this a few drops of caustic potash, and then, by means of a pipette, drop by drop, a ten-per-cent. solution of copper sulphate. The green color produced becomes a violet on addition of the last reagent. This is known as the biuret reaction. Propeptone would not form without hydrochloric acid being present. Failure to obtain a positive test for free hydrochloric acid, followed by a positive biuret reaction, indicates the presence of combined hydrochloric acid.

Quantitative Tests.—The total acidity is made up by the acidity from mineral and organic acids in a free or a combined state. Normally, this forms rarely more than 0.25 per cent., though, according to the time after meals, this varies, the most being found three hours or so after a mixed meal.

A decinormal solution of NaOH is used in a burette. Ten cubic centimetres of filtered contents of the stomach are placed in a beaker and one or two drops of phenolphthalein are added as an indicator. Excess of alkali renders the color red. The NaOH solution is added till the red color appears in the gastric contents, and the amount necessary to produce this result is read off on the burette. Normally from 4 to 6 c.c. are required for 10 c.c. of gastric contents; *i.e.*, 40 to 60 c.c. would be necessary for 100 c.c. Hence one speaks of forty to sixty per cent. total acidity. The exact amount of acid is calculated as follows:

1 c.c. of normal NaOH = 1 c.c. normal HCl.
1,000 c.c. of normal NaOH = 1,000 c.c. normal HCl, *i.e.*, 36.5 (molecular weight of HCl in grams to 1 litre of water).
∴ 1 c.c. of normal NaOH = 0.0365 HCl.
∴ 1 c.c. of decinormal NaOH = 0.00365 HCl.
∴ 40 to 60 c.c. of decinormal NaOH = 0.146 per cent. to 0.219 per cent. (= normal percentage of total acidity).

For all practical clinical purposes this test suffices and gives a fair idea of the proportion of hydrochloric acid present, inasmuch as most of the acidity present is due to this acid.

Test for Free Organic Acids.—Lactic acid: Uffelmann's test is the simplest, and, though not infallible, is, on the whole, the most practical. A solution is made consisting of one or two drops of Tinctura ferri perchloridi and 10 c.c. of a 1-to-40 solution of carbolic acid. This forms an amethyst blue color (if darker it should be further diluted with water); a few drops (ten or fifteen) of the filtered stomach contents are added to this solution, and if lactic acid be present the solution will show a greenish-yellow or canary-yellow color. (Anything less than a definite yellow tinge is without meaning.)

Inasmuch as combined hydrochloric acid is apt to give a yellowish-brown color with this solution, it may at times serve better to omit the carbolic acid and use merely a couple of drops of dilute iron perchloride. Lactic acid added to this more or less colorless solution gives a light yellow tint. (Phosphates, sugar, and alcohol must be excluded, as they give a similar reaction.—Gillespie.)

The Volatile Organic Acids.—After distilling off three-quarters of the stomach contents, the rancid butter smell of butyric acid and the characteristic acetic odor of acetic acid are readily detected. The more elaborate means of detecting them are of little value.

Examination for the Enzymes.—The ferments are much more constant than is the hydrochloric acid, as they are uninfluenced by circulatory or nervous disturbances, and any persistent alteration in their quantity or action implies a greatly altered function of the glands of the stomach. They assume importance only when hydrochloric acid is deficient. By knowing of the presence of enzymes, we can tell if the glands are temporarily or permanently damaged. Absence of hydrochloric acid is common in many gastric conditions, but is unaccompanied by any appreciable change in the secretion of pepsinogen. When the latter is absent it implies an advanced gastritis or atrophy of the mucous membrane. A knowledge of the enzymes thus affords us aid in prognosis and treatment, though the value thereof is certainly limited.

Test for Pepsinogen.—It is converted into active pepsin in presence of HCl, and thus can convert albumins and albuminoids into soluble substances.

Qualitative Test.—If the filtered contents of the stomach contain HCl and digest albumen, pepsin is present; or if, having no HCl, they digest albumen after HCl is added, pepsin is present. If the filtered contents have no HCl and do not digest albumen after HCl is added, then pepsin is absent.

Quantitative Test.—Add to 10 c.c. of stomach contents a small egg disc or dried fibrin, and place in a thermostat at 37° C. The egg or fibrin will become dissolved. According to Jaworski, 5 to 6 c.c. of egg disc added to 25 c.c. normal stomach contents (filtered) will digest in three hours. This is a fair quantitative test. Hammerschlag's is more accurate: Make up 20 c.c. of one-per-cent. albumen solution, containing three per cent. HCl, and divide into two test tubes. To the one (the control) add 5 c.c. H_2O, to the other add 5 c.c. filtered stomach contents. Let stand one hour in an incubator at 37° C., and test the amount of albumen by Esbach's method. The control contains the original amount of albumen, the other less, and the difference between them represents the amount of albumen digested; *e.g.*, if the control has six per cent. albumen and the other three per cent. albumen, then we have fifty per cent. of albumen digested.

The Rennet Ferment (Labzymogen).—This ferment clots milk even in faintly acid or neutral media. The simplest test is Leo's: Add three to five drops of filtered contents to 5 to 10 c.c. of milk; place in the thermostat, and clotting will occur in fifteen minutes.

The Motor Power.—The fasting stomach contains but little fluid. The highest estimate places the amount at 100 c.c. Most authorities regard 20 to 30 c.c. as the normal. This fluid is pure gastric juice and should have normally no food residuum. The tests suggested for this have been very numerous. The best and one of the simplest is to ascertain from a test meal the amount of residue in a given time. Thus, one hour after the test breakfast there should not be more than 100 c.c. of contents; two hours after the meal of Germain Sée there should not be more than 175 c.c., while five hours after Riegel's meal 200 c.c. would be regarded as the limit for a normal stomach. Anything exceeding this implies deficient motor power. There are three degrees of motor insufficiency:

1st. The stomach contents are delayed, but evacuated some time before the next meal.

2d. The stomach is empty only just before the next meal or in the early morning. This is stagnation.

3d. The stomach is never completely empty even in the early morning. This is called retention.

The smaller test meals will suffice for diagnosing the first two conditions. To test for the third degree it is well to wash out the stomach at first before giving the Riegel dinner (which should be administered in the evening), and then again to test in the early morning for what residue may be present. If food has remained, the third degree of motor insufficiency is present.

II. MINOR AILMENTS.

General Symptomatology in Diseases of the Stomach.

Indigestion or Dyspepsia.—These terms may reasonably be applied to a series of cases which every physician meets, and that very frequently—cases which, though probably associated with a slight temporary anatomical, secretory or other functional abnormality, nevertheless show little or nothing upon careful physical examination of the stomach, nor any serious alteration in the chemical constituents of its contents after a test meal. Nor, again, is it other than an admission of ignorance to assign these cases in all instances to a pure neurosis.

In health we are unconscious of the presence of digestion and do not realize the fact that we possess a stomach. When dyspepsia occurs, however, much of what we eat occasions such inconvenience as to make us only too cognizant of the fact that digestion is in progress, and that we possess a digestive organ which is functioning badly. The disturbances are usually present after eating, and are most frequently associated with some temporary derangement of the motor or secretory powers. They may appear before meals and be relieved by eating; and, when such is the case, the causative factor is usually an increase in the amount of acid secreted. Sometimes, again, the nerves alone seem accountable for the disturbance, while at other times a defective circulation from organic or functional cardiac disease, or vasomotor trouble, is the main etiological factor.

The symptoms most frequently present are as follows: A bad taste in the mouth with a disagreeable odor of the breath; a coated tongue; anorexia, or more rarely boulimia; oppression and weight in the stomach; flatulence and a sense of distention; pains of various characters; heartburn, pyrosis, water brash, acid eructations; nausea and vomiting; dyspnœa and palpitation; cough; constipation and diarrhœa; vertigo.

Any or most of these symptoms may be present with serious disease of the stomach, in which case they may be the main premonitory signs; or, on the other hand, they may be merely the symptoms of an ordinary dyspepsia of a purely temporary character.

The Causes of Simple Indigestion and Minor Ailments of the Stomach.—1. *The Food.*—The *quantity:* This should be sufficient to supply the demands of nutrition, and in order to maintain a normal digestion this should be neither too much nor too little.

Excessive Quantity.—In childhood, when too much is persistently taken, the effects are of a less serious consequence than in adult life.

Excess of food is injurious in various ways: the stomach having too much to do is easily overworked and the muscle becomes to some extent paretic. As a result it never completely empties itself, and is kept persistently busy without the necessary rest. This of course is particularly injurious at night, for which reason the custom of taking heavy suppers is baneful, all the more so as digestion is delayed during sleep and the overloaded stomach has a double reason for becoming diseased. The fact that many people can stand excesses in diet for years with impunity does not render this rule any the less true. Usually such dietetic errors are amply paid for in the latter years of life, even though individual predisposition may count for much, as also the habits of life in general, the occupation, and the daily hygiene.

Excess of food is not always the result of individual large meals, but often the consequence of a too rapid succession of individual meals, or their irregularity and multiplicity.

Insufficient Quantity.—Too little food, on the other hand, is not an infrequent cause of dyspepsia, the so-called starvation dyspepsia. It is often the outcome of some other digestive trouble, whereby the patient imagines that a strictly limited diet is necessary, not wholly as regards quality but likewise as regards quantity. Rich and poor alike suffer from this cause; the rich from errors of judgment, the poor from necessity, often laboring without a quantity of food sufficient to keep up the metabolism.

In some cases of dyspepsia it is advisable to give small and frequent meals, but such should always be given with due regard for their caloric values. In all cases, whether food is given in limited amounts or in excess to satisfy the needs of the patient, regularity in the time of meals should be carefully considered, in order to give the stomach its proper time for rest.

The Quality of the Food.—This is of equally great importance. The digestibility of foodstuffs depends upon the quality, both chemically and physically. Thus, for example, the food should never be so tough as to render complete mastication difficult; hence the need of avoiding foodstuffs which are too coarse or of too hard a fibre (as in the case of meat when old), or insufficiently cooked. Mastication is thus rendered difficult, and the saliva and secretory juices fail to come into contact with the individual particles. These undigested masses remain thus irritants to both the stomach and the intestines.

Such a condition of course is aggravated by imperfections or absence of the *teeth*, more especially the molars.

The *cooking* of the food is of the greatest importance. It is a well-recognized fact that boiling renders meats more digestible than does any other form of preparation, and for the simple reason that they thus become more disintegrated. Roasting and broiling come next in importance, while frying prepares meats and other foods in their most indigestible form. Fried foods are covered over with fat, which thereby renders them more or less impermeable to the juices of digestion.

Again, too much of *one kind of foodstuff* is likewise bad. Thus, for example, an excess of proteids over any other kind of food would exact too much of the gastric juice, and thereby both directly and indirectly injure metabolism. Upon the other hand, if carbohydrates be taken in excess, fermentation is apt to occur and organic acids are introduced in excess into the alimentary tract.

The *temperature* of foods is likewise of some importance, and excesses here, as in other particulars, are injurious. Food when taken too cold, as in the shape of ices and ice water, interferes with the proper functions of the stomach, as do also foods of various kinds when taken persistently too hot.

The ingestion of too much fluid is bad, as it renders the food pappy in the mouth, dilutes the gastric juice, and thereby increases the liability to fermentation and indigestion. Much fluid is particularly injurious in motor insufficiency, which is termed by some the dyspepsia of fluids, for in this condition fluids are with difficulty passed on into the duodenum and the water is itself not absorbed in the stomach.

On the other hand, where hydrochloric acid is secreted in excess and the motor power is good, water taken freely with meals is of benefit, diluting the excessive acid present and relieving the distressing symptoms.

A glass of hot water taken before meals, or a glass of cold water in the early morning, even for healthy people, will aid digestion.

There are many foods which custom impels us to take but which should be classed among those which are a menace to healthy digestion; such, for example, as foods which are too rich, or again too spicy, in which category we place excess of vinegar, the persistent use of pickles, and the like, which induce a chronic dyspepsia and consequent emaciation from malnutrition.

The same holds true of acid wines. Spirits, too, in excess are to be condemned, especially when taken on an empty stomach. In those in whom flatulence is common beer is injurious, especially so if recently brewed, because fermentation is thus incomplete, and is continued after the beverage has found its way into the stomach.

Tea should always be taken weak; when long infused it contains an excess of tannin, which being an astringent interferes with the secretions of the stomach, especially with the digestion of proteids.

Unripe fruit, being mainly tough cellulose, is likewise irritating.

2. *Bacteria.*—These at times contribute toward indigestion. Their invasion of the teeth and mouth, if not prevented or contended against, is liable to produce slight functional disorders, among which loss of appetite, a disagreeable taste in the mouth, fermentation in the stomach and its consequences, may here be mentioned.

3. *The secretory or motor power* of the stomach itself may be defective, temporarily and only to a slight degree, acting thus as the main factor in dyspepsia.

4. *The nervous system* may be a primary etiological factor. Excitement, emotion, grief, etc., may each contribute toward the production of a more or less ephemeral indigestion.

5. *Circulatory disturbances,* associated with organic or functional disturbances or vaso-motor conditions, may each in themselves act as causes.

6. *Malposition of the viscera, adhesions within the abdomen,* etc., may act in the same way.

7. *Inactivity* is a very important factor, resulting as it does in imperfect combustion and its results.

Symptoms in Detail.

Coated Tongue.—The tongue may be coated with a fur of varying colors, from a whitish hue to a brownish black; its thickness may vary in degree, as also its consistence and moisture. The coating is made up mainly of epithelium, bacteria, and detritus. It may be localized at one or other parts of the tongue. It is a fallacy to believe that the tongue is a mirror of the stomach, for in a large majority of cases faulty digestion in the stomach has but little to do with the coating seen upon the tongue. Much more frequently are the causes to be found on the teeth or on the pharynx or tonsils. Frequently a stomatitis is the main cause, or, again, excessive smoking.

Under other conditions a coated tongue may be due to disease of the stomach and intestines; it does not as a rule carry any diagnostic value. In many diseases of the stomach, which are of extreme gravity, the tongue is clean. This may frequently be the case with ulcer of the stomach or with a condition of hyperacidity, in which case the tongue is especially clean at the tip, and often is quite sore. In alcoholics too there is often a reddened sore tongue which is uncoated.

The Breath.—The breath may be foul or disagreeable, and this may be subjective, obvious only to the patient; or it may be objective, *i.e.*, only the patient's friends observe the affection. At times the condition is associated with defects in the mouth, pharynx or larynx, and respiratory passages. The odor may arise from the stomach. It may be of sulphureted hydrogen and due to the occurrence of putrefaction or decomposition in that organ. Sometimes this is accompanied by eructations of either gases or liquids, while at other times no obvious cause can be found to account for the peculiar disturbance.

The Appetite.—Though related to gratification of the nerves of taste in the mouth, and usually an expression of the need of the body for food, the appetite, when abnormal, may be merely an indication of the need of the gastric juice, or again an evidence of a perverted nervous system, or of an altered state of the metabolism. In health it is a definite indication of the caloric requirements. Just exactly how the sensation of appetite is induced is unknown. It is a nervous phenomenon associated with the brain, and dependent in a reflex way often on conditions of the stomach. Perhaps, as Brunton suggests, it is connected with distention of the lymphatic spaces in the mucous membrane, analogous to the itching which appears before sweating takes place. Some regard the swallowing of the saliva and its stimulation of the gastric secretions as the main factor.

The state of the circulation, however, seems to have some influence upon the appetite, and Beaumont has shown that a craving for food was present when the mucous membrane of the stomach was red. Variations again may be due to alteration of the nerves of taste and to disease in the mouth itself.

Anorexia (ἀν, ὄρεξις), diminished appetite, depends on many conditions. Many people eat too much and too often, a result being that these excesses soon lead to an impairment of the appetite.

The cause may be (*a*) in the stomach, (*b*) in the nervous system, or (*c*) in constitutional conditions.

(*a*) So far as the stomach is concerned, motor insufficiency is the most important factor, unless increased hydrochloric acid be present.

Other causes, again, are organic disease of the mucous membrane, acute and chronic gastritis, cancer, atrophy of the glands, etc.

It is important to remember that in cancer the appetite may remain good if the motor power be unaltered, especially in cancer of the body of the stomach, and the patient may even gain in weight.

Sometimes in disease of the stomach it is not so much the diseased condition as the fear of pain which induces anorexia—such, for example, is the case in gastric ulcer.

(*b*) With regard to the nervous system as a cause there may be past associations, nauseous tastes, smells, etc., or again excitement, shock, or grief, for it is well known that excessive mental exercise, worry, and the like impair the appetite.

In insanity, again, anorexia is a well-recognized symptom in many cases; in gastric neuroses diminution in appetite usually implies diminution in the function of the stomach as well. Professional fasters may come under the last category, having habituated their stomachs to less requirements, and to some extent losing the real desire for food, though the metabolism is bound to suffer in consequence.

(*e*) With reference to the constitutional conditions tuberculosis is an important one—in fact, of so great importance that any marked anorexia without any apparent cause should always suggest a careful examination of the lungs.

In fevers and the various infections, anæmias, cachexias, and wherever there is excessive tissue waste, anorexia is a frequent coincidence. An exception to this last is diabetes.

Excessive physical exertion has the same effect. Lastly, poisons formed in the intestines or in the tissues and excreted into the stomach may disturb the appetite, as frequently occurs in such conditions as uræmia.

It is well to remember two important facts: First, in endeavoring to obtain a history from the patient, his statements in regard to anorexia are apt to be unreliable; second, patients often take too little in disease of the stomach, especially in neurosis, and emaciation is the natural result. Some one has truly said that in gastric diseases more harm has resulted from treatment by starvation than from overfeeding.

Excessive Appetite.—In this there are two different conditions: (1) Boulimia (βους, λιμος, oxen hunger), by which is meant increased appetite for food, also called cynorexia. (2) Polyphagia, meaning excessive eating, whether or not the appetite is increased.

Increased appetite may depend on various factors—the condition of the stomach, for example, and especially the presence of hyperacidity. It is therefore often a noticeable symptom in gastric ulcer, in which disease there is apt to be increased acidity, provided of course the pain does not create the fear of eating. It may depend on nervous influences, being often due to an irritable condition of the centripetal gastric nerves. A mental stimulus is in itself sufficient; at other times there may be a neurosis, or hysteria, or neurasthenia, or insanity.

Polyphagia seems more or less natural with some individuals; it is common in children. It is often associated with the presence of intestinal worms, or, again, children through faulty training and bad management are forced to eat when they really do not require food. Polyphagia occurs frequently in brain affections, particularly tumors, in sexual disorders, in convalescence from various fevers, especially typhoid, and lastly in diabetes.

Parorexia, or altered appetite, is a neurosis. Apart from an excessive or diminished diet there is a desire for unusual foods and substances which do not come at all under the category of foods.

Thirst.—An increased desire for fluid depends less on the condition of the stomach than does hunger.

The quantity of fluid imbibed during the day varies according to the individual. It naturally should have some relation to the solids, but this too is uncertain.

The physiology of thirst is ill understood. It seems to be connected somehow with diminished fluid in the body; it is probably a nervous phenomenon expressing a demand for water in the tissues to distribute salts between the tissues and the blood, and thus to maintain a proper metabolism. It occurs, first, where there is increased excretion of water, *e.g.*, through the skin (sweating), in physical exertion, in tuberculosis, etc.; through the kidneys—in diabetes mellitus and insipidus, in chronic Bright's disease; through the bowels—in diarrhœa, dysentery, cholera, etc.; through hemorrhages, through vomiting, etc. Again, it occurs in gastric disorders—from faulty diet, *e.g.*, excessive salts, spices, alcohol, etc., because more fluid is excreted by the mucous membrane than is absorbed; or there may be interference with the absorption of fluids, as occurs, for example, in gastrectasis, especially from stenosis of the pylorus. In such a condition there is marked motor insufficiency, and therefore a notable alteration exists in the relation between the amount of water taken and the quantity of urine excreted. Then, too, it occurs in gastritis secondary to alcoholism or to Bright's disease, in ulcer of the stomach, gastric neuroses, supersecretion, etc.

The sensation of thirst is mainly in the back of the mouth and fauces. To allay it, absorption of fluids is necessary. Hence the great thirst in gastrectasis, where the muscle is so diseased that though much fluid is taken none is pushed into the duodenum, and therefore none is absorbed.

Stimulation of saliva by acids also helps to allay thirst. On the other hand, too much water often hurts digestion, and, vice versa, in some conditions it helps greatly, as, for example, in gout, rheumatism, and many general infectious diseases, where a flushing out of the tissues occurs in this way.

Pain.—Two features of importance should be remembered in this connection:

1. Pain in the stomach, so called, especially that which occurs after meals, is more often merely a sense of weight or discomfort.

2. Oftener than not, pain in the stomach, so called, is really in the intestines, perhaps the colon, or more rarely in the gall bladder or associated with renal calculi, neuralgic conditions, or muscular rheumatism.

Pain when really in the stomach, however, is often a valuable sign, and one should ascertain details in regard to its locality, intensity, time of onset, general characters, etc. It is well to remember that many gastric diseases are quite painless; that in other cases, on the other hand, pain is a mere incident of such a disorder, for example, as simple meteorism.

Site.—When associated with gastric digestion the pain may be in front. This occurs in dyspepsia with atony of the stomach, and with distention, ulcer, gastroptosis, etc. It occurs in the back in ulcer chiefly; between the shoulders in ordinary dyspepsias of all mild forms; in the chest in cardialgia, whether hyperacidity, hypersecretion, or gastric ulcer be present, or not. It is in the left side or in the axillæ, more commonly, when there is distention or flatulence.

The intensity may vary; it is more severe in ulcer, cancer, great distention, and acute gastritis; it is more mild in atony and chronic gastritis.

As regards the time of onset, the pain may be periodical as in gastroxynsis, or chiefly after eating as in cases of ulcer, gastric or duodenal, and of cancer; or it may appear long after eating, and particularly before a subsequent meal, as in hyperacidity. It is continuous chiefly in cancer.

The general characters refer, for example, to the burning of hyperacidity, the boring pain of ulcer, and the dragging pain of gastroptosis.

The cause may be either a direct irritation or simple nervousness, or the pain may be associated with some general disease not primarily gastric, as is the case in anæmia, chlorosis, tuberculosis, malaria, acute diseases of the central nervous system; more especially in tabes, myelitis, multiple sclerosis, and neurasthenia.

Again, pain may occur as a local neuralgia, the so-called gastralgia, in which condition the indications point less to the need of dietetic treatment than to that of rest and of other general measures.

Heart-burn, Cardialgia, Water-brash, and Pyrosis.—These terms, while differentiated by some, are very apt to be used more or less as synonyms. In the case of heart-burn and cardialgia the pain is the prominent feature, while where water-brash and pyrosis are present there is apt to be an associated regurgitation of fluid. Small quantities of fluid, sometimes acid, sometimes alkaline, are regurgitated along the œsophagus and into the pharynx, where they are tasted. The acids are usually organic acids, and the taste under such conditions is apt to be mawkish rather than burning.

The fluid may be alkaline from saliva, which is excreted at first because of gastric irritation, then swallowed, and again rejected from the stomach.

Sometimes gases alone, chiefly ammonia, cause this condition. According to Ewald, it is purely a motor neurosis, while according to Brunton the lower end of the œsophagus is protruded into the stomach like a prolapsed rectum, and being sensitive, is irritated by the greater acidity of the stomach contents.

The relief for this condition is obtained usually by a proper diet, suitable to the acidity, by the administration of bicarbonate of soda, by suitable purgation, and, if fermentation be present in any large amount, by the employment of lavage. It is only in very severe cases that opium is indicated.

Flatulence implies expulsion of gas from the stomach, and is due to the presence of too much gas in the organ. There are two or three ways in which it reaches the stomach:

1. By the swallowing of air, either associated with the saliva, in which carbonates are present, or with food containing carbonates, or with effervescent drinks.

2. The air may be generated in the stomach, either through fermentation or decomposition, or possibly through the separation of gases from the blood, or through the exchange of CO_2 and nitrogen; or, lastly, it may come from the secretions of the glands.

3. Air may be regurgitated from the intestines into the stomach, as has been demonstrated both experimentally and practically.

In atony of the stomach gas readily accumulates and fermentation is favored; often in neurotic people flatulence is persistent, with perhaps evidence of gastralgia. The gas ejected is usually odorless, and if acid eructations are present they are usually due to the organic acids present. The condition is not infrequently associated with supersecretion of hydrochloric acid. If putrid gas-like sulphureted hydrogen be ejected, one may conclude that fermentation and decomposition are taking place. This gas formation, however, is so uncommon in cancer of the stomach that some authors attach some diagnostic value to the fact. Marsh gas is not infrequently formed in the stomach and likewise expelled.

Borborygmi is a name used to imply the presence of air and peristaltic movements of the stomach and intestines, coming as it does from the Greek word βορβορύζω, "I have a grumbling in the bowels." In some cases this flatulence yields readily to treatment when the causative factors, such as dietetic errors with too much starchy foods, are removed, when the neurosis is properly treated, or when, as the case may be, decomposition or other disturbances occur in the gastric digestion. For the immediate relief peppermint, carbonate of magnesia, and bismuth preparations with bicarbonate of soda, are perhaps the most suitable. In some cases I have seen persistent relief obtained from the use of ordinary essence of pepsin. When constipation is present the bowels should be regulated.

Vomiting.—This is expulsion of the gastric contents through the mouth. This must be distinguished from retching, which is an effort at vomiting, due to the contraction of the gastric muscles together with the diaphragm and the abdominal muscles, the cardiac end of the stomach being closed or the stomach itself being empty.

It must be distinguished too from regurgitation, which implies simply the flowing back, as far as the pharynx, of food, liquid or solid, through the stomach; while rumination, corresponding to chewing of the cud, implies not only regurgitation of food, but the subsequent mastication and reswallowing.

True vomiting as it affects the stomach is due to local causes, and is to be distinguished from various other forms, of which the two chief ones are the central and the reflex vomiting.

The *central vomiting* is due to direct stimulation of the vomiting centre, which is in the medulla, and it occurs usually without the usual premonitory signs which accompany true vomiting, or with only a few of them. These premonitory signs are usually yawning, pallor, depression, sweating, salivation, nausea, etc.

Certain drugs induce vomiting, as, for example, tartar emetic, apomorphine, and ipecac. So, also, do various cerebral diseases—tumor, meningitis, and injuries to the medulla oblongata.

Sympathetic causes come under the same heading, as, for example, associations, sensory impressions, seasickness, etc., and lastly, the vomiting of hysteria and neurasthenia.

Reflex vomiting is that which is induced in a great variety of maladies, of which a few may be here cited as examples: Bronchitis, tuberculosis, and emphysema, in which either the cough or the expectoration is liable to induce the vomiting; pharyngitis, especially in alcoholics, where the mucus collected over night is swallowed into the stomach and induces the morning vomiting of drunkards; gall stones and renal calculi, particularly with great pain; strangulated hernia; diseases of the genital organs; severe pain anywhere in the body, and toxic conditions like uræmia. The onset of acute infections, especially in children; pregnancy at certain periods in its course; the chronic form of certain metallic poisons, like arsenic, lead, etc., and Addison's disease—all these are accompanied at times by a vomiting which cannot be classified as any other than *reflex*.

In *true vomiting*, on the other hand, there are premonitory signs. The patient becomes dizzy, pale, often the pulse increases, retching may follow, and then comes the onset of the vomiting. This has sometimes a definite relation to food. If it occurs after meals and is not due to a neurosis, it implies an organic disturbance of the tract; it may be due to ulcer, some inflammation, atony, cancer, stenosis of the pylorus, supersecretion, etc. Sometimes it comes on at once after meals, and sometimes again only several hours later, as occurs chiefly in atony and dilatation of the stomach.

Sometimes, as already mentioned, it occurs only in the early morning (the vomiting of drunkards which is usually associated with pharyngitis), while in supersecretion the vomiting occurs either early in the morning or during the middle of the night.

Periodicity in the vomiting is likewise a not infrequent occurrence in several diseases, such as dilatation of the stomach, where it may be present every two or three days, and then it is usually copious in amount.

The vomitus varies according to the cause, the food, the time, the nature of the gastric conditions, etc. One must note the amount of digestion undergone by the individual foodstuffs, notably the proteids and starches; also the presence of food taken more than seven hours previously, which in itself is an evidence of some dilatation.

There may be pus, blood, bile, saliva, and mucus present, and the color may be the same as that of coffee grounds. This color is frequently due to altered blood, but may have some relation to the previous nature of the food—blueberries, currants, etc.

The odor of the vomitus is comparatively unimportant except in intestinal obstruction, where it, of course, is apt to be fæcal in character.

The taste varies; it may be often acid and burning, or simply that of the food taken; but when decomposition has occurred it may be putrid in character.

It is also of some importance to ascertain if the vomiting gives relief, as various diseases are thus in part differentiated.

The quantity of the vomitus is of decided importance. It is considerable in stenosis of the pylorus with dilatation of the stomach; it is usually small, on the other hand, in chronic gastritis and ulcer, unless marked gastrectasis be concurrent.

Dyspnœa.—This is not uncommon in indigestion and is associated with distention of the stomach and pressure upon the diaphragm, as well as with interference with the ordinary movements of the heart. Usually if the dyspnœa be marked there is some graver underlying condition, such as anæmia, asthma, cardiac disease, etc. It may occur every few hours or only after several days, and is accompanied by a sense of fear and oppression, and usually by some palpitation.

Palpitation.—The anatomical relations of the heart and stomach play only a small part in the causation of palpitation. As a matter of fact, this sensation does not often possess much significance. The more serious form of palpitation is often associated with myocarditis or with angina, and under such conditions a heavy meal is not infrequently followed by a fatal syncope.

Tachycardia is comparatively rare, and when present is usually paroxysmal. It is more frequent after middle age, at the menopause, in neurotic, anæmic, or cardiac patients, and in those too who are habitués of tea and tobacco. It is more frequently present with flatulence.

Drowsiness.—This may be present either after meals or at any time, and is directly due to the relative anæmia of the brain from the extra demand, on the part of the stomach, for circulating blood.

Insomnia may be due to a coincident organic disease of the brain, etc., or to sleeping during the day, or, again, it may be due to motor insufficiency of the stomach, the remains of food being carried on into the night. The insomnia may be a temporary affair merely, or it may be chronic. A late supper may be very slowly digested during sleep, therefore not only is there insomnia but restlessness, and bad dreams are very apt to follow.

Vomiting frequently gives relief in such cases, and when this cannot be induced, lavage will have the desired effect.

Vertigo.—This symptom may be of little or of grave significance. The simple condition is not very uncommon in cases both of acute and of chronic indigestion, when the stomach is either full or empty. Milder forms occur after meals or upon exertion, or even when the patient is at rest. The vertigo is momentary in time, and there is neither fainting, falling down, nor coma. It may be accompanied by nausea and vomiting or some other digestive disturbance, and the taking of food not infrequently relieves the symptoms. Its sudden onset is rather characteristic.

One should be careful to exclude the more serious causes of vertigo, *e.g.*, Ménière's disease, an incurable condition in which there is usually deafness in one ear and a sensation of circular movements; petit mal, in which coma and perhaps alternating convulsions are present; tumor of the brain, which has its special signs, as have also tabes, ataxic paraplegia, cardio-renal disease, anæmias, errors of refraction, etc.

Cough.—In indigestion cough is usually associated with some irritation of the throat from pyrosis, and is more especially apt to occur if the tonsils be enlarged or a pharyngitis be present. A distended stomach pressing on the diaphragm may, by mechanical means, induce a cough, but perhaps the most common cause of cough is that which is associated with the ingestion of meals—in various pulmonary disorders, in chronic bronchitis and in emphysema, for example, where the diaphragm is less active and there is defective oxygenation of the blood, and when more mucus collects. For this reason, too, large meals are more apt to cause a cough than small ones. Then, again, the cough may be reflex, as is the vomiting too, as already mentioned in speaking of tuberculosis.

The General Treatment of Indigestion.—The first essential for a good digestion is a proper daily regimen. A suitable environment, physically, mentally, and climatic, is what renders the ordinary health resorts with their regular routine of life so excellent in the treatment of chronic forms of ordinary dyspepsia, and neither the specific drugs nor the specific waters can be said to confer one-half the benefit which accrues to habitués of these sanitaria.

In addition to this, the wearing of proper clothing is an essential element. Clothes worn too tight, and corsets too much laced, interfere with the action of the diaphragm, of the stomach and liver, and in this way easily induce dyspepsia.

The occupation of the patient must likewise be considered; it should, as far as possible, be in every respect free from mental strain or anxiety.

The number of meals should be regulated, as should also the intervals between them. The food should be taken slowly, for digestion in the mouth is extremely important. Mastication and insalivation are essential to proper digestion, and the teeth should therefore be duly cared for.

Rest and exercise should be carried out in accordance with the needs of the case. After each meal and also before meals, it is well for everybody to rest a short time; at other times exercise, if moderate, aids digestion; the gastric motor power becomes more quick and the intestines act more readily. While this is true of healthy people, it is all the more important in cases of disease. After heavy meals all persons should rest, and, later on, they should exercise in the open air. Rest is most essential in cases of gastroptosis, gastrectasis, hyperacidity, and cancer. Not only should the rest be physical but it should also be mental.

As regards the dieting, the prophylactic measures in this respect have already been mentioned, and each case must be treated on its own merits, in accordance with the views already expressed or to be mentioned.

Too much fluid should never be taken with meals, while before meals a glass of water, particularly hot water, is of benefit.

Frequently warmth is of benefit to some patients, and for this reason, and this only, does one obtain relief from the use of flannel belts about the abdomen.

The *medicines* which are given are perhaps the least important features in the treatment of dyspepsia. To stimulate the secretory and motor power of the stomach when necessary, and to lessen decomposition, are the main factors of use in medicines. As a rule, it is not possible by medicines to accomplish much even in this respect, though other measures, mechanical or dietetic, may be helped by the judicious administration of certain drugs.

Medicines which are intended to increase the appetite and stimulate secretion are numerous, and stomachics, as they are called, are variously lauded or frowned upon by the specialists. Reichmann holds that the use of bitters upon an empty stomach—no matter whether its secretion be normal or abnormal—exerts no immediate effect upon these secretions; it is only a little later that bitters stimulate them somewhat. When taken with the food they interfere with gastric digestion. Riegel strongly recommends the use of condurango bark, while others again successfully employ orexin to stimulate the secretion. This last drug, however, is frequently followed by disagreeable symptoms, such as nausea and vomiting.

A favorite prescription of the English authors is the following: Sodium bicarbonate, gr. x., tincture of gentian, ʒ ss., and peppermint water, ℥ i., three times a day before meals.

When too much secretion is present, on the other hand, powders of bismuth and soda, with perhaps some powdered nux vomica and compound cinnamon powder, may give relief, as recommended by Brunton, both because of their sedative action and from the fact that such powders in bulk the more readily absorb acids.

The Use of Acids, especially Hydrochloric Acid.—It is now well established that the hydrochloric-acid secretion of nature cannot be artificially replaced. If hydrochloric acid is absent from the stomach contents, one cannot administer it artificially so as to get the free acid back after a test meal. Nevertheless, its use, where hydrochloric acid is absent, aids in promoting the digestion of proteids; it should be given with a glass tube after meals, or as a stomachic one-half hour before meals. It is contraindicated when hydrochloric acid is in excess.

The Use of Alkalies.—Reichmann's experiments show that sodium bicarbonate, taken either on an empty or on a full stomach, has no influence whatever on gastric secretion, but it lessens total acidity, that is, it acts upon the juices abnormally secreted, as takes place, for example, in hyperacidity, hypersecretion, and gastric ulcer, where it is useless to stimulate the secretion. One should never give alkalies unless hydrochloric acid is the cause of the acidity; it should also never be administered where organic acids are present. An excellent way of administering alkalies is in powder form, combining sodium bicarbonate, calcined magnesia, and powdered cinnamon, they may also be given in the form of Carlsbad salts, or of Kutnow's powder, in the early morning before breakfast.

The Use of Pepsin.—Pepsin is employed in various forms: powder, pill, combined with hydrochloric acid, in fluid essence, and as various tinctures. The pure article, the so-called absolute pepsin, is by far the best; it should be given in doses of from five to fifteen grains; the official preparation is given in doses of from thirty to forty-five grains. Most preparations of pepsin, it may be said, are unreliable. Those which are combined with various alcoholic media are useless, except for the alcohol which they contain, and which is largely responsible for the aid which they give to digestion. Technically and *in vitro*, there would seem to be no benefit, or but little, from the use of pepsin. There is always enough secreted even when the hydrochloric acid is plentiful, as well as when it is deficient in quantity

The indications for the use of pepsin are found in those conditions in which it is either deficient or absent Now if it be deficient, the only requirements are medicinal amounts of hydrochloric acid to make the pepsin active. If, on the other hand, pepsin be entirely absent, so much hydrochloric acid is required to make the pepsin active that it is impossible to administer the drug in that way. However, it must be admitted that one often meets in practice instances in which the benefit derived from the use of this drug is undoubted, the fluid essence perhaps being the most suitable preparation of all.

Pancreatin.—Pancreatinized foods are used where hydrochloric acid is deficient, in order to aid intestinal digestion. The powder acts on the stomach itself, and its value is probably confined to cases such as those mentioned. Unfortunately, most of the preparations when tested are found to be negative. Some, however, made by the more reliable firms are good, and are used in pellet form with sodium bicarbonate.

Saliva is never much diminished in indigestion, but a very great excess of hydrochloric acid causes it to lose its activity, and under such conditions *ptyalin* is sometimes of benefit.

The preparation known as *takadiastase* acts in the presence of even 0.05 per cent. of hydrochloric acid, and hence is apt to be better than others, which act in only 0.01 per cent. of hydrochloric acid.

When much decomposition occurs in the stomach, lavage is probably of much more use than medicines. The medicines, however, which give considerable relief for this disorder are *thymol*, which is prescribed in minim doses with alcohol, and *creosote*, which may be given in the form of the carbonate, or pure, as a pill.

III. MOTOR INSUFFICIENCY.

1. *Relative* or symptomatic, as in stenosis of pylorus (*q.v.*), or in cancerous or benign obstruction. This may be atonic or hypertonic.

2. *Absolute*, as in idiopathic dilatation, simple atony, atonic dyspepsia, simple gastrectasis.

Definition.—Motor insufficiency is a relative or absolute lack of power on the part of the muscular wall of the stomach to propel the food through the pylorus within the normal time.

(For relative insufficiency see paragraphs on stenosis of the pylorus, carcinoma ventriculi, etc.)

Absolute motor insufficiency, or idiopathic dilatation, has two periods:

1. *Stagnation*, which has two forms: mild atony and severe atony. In stagnation there is delay in evacuation of the stomach contents. In mild cases the stomach becomes empty between any two successive meals; in severe cases it is empty only in the early morning.

2. *Retention*.

Etiology.—(*a*). Excessive work for the stomach is the essential cause. Such excessive work is inflicted by deviations from the normal diet; *e.g.*, the taking of food which is faulty as regards quantity, quality, or mode of preparation.

(*b*) The propelling power may become weak through other causes, *e.g.*, hereditary weak stomach; trauma or peritonitis may weaken the gastric muscle; wearing improper clothing; prolonged sedentary habit; disease of the stomach itself; organic changes in the muscular coat; ulcer or cancer in other parts than the pylorus, apart from stenosis; chronic gastritis; degenerations—fatty colloid, or amyloid; cirrhosis of the stomach; the use of narcotics and of alcohol; constitutional troubles, *e.g.*, chlorosis, anæmia (Collier's stomach, as described by C. Allbutt), tuberculosis, typhoid fever, and nervous troubles. Great anxiety or grief may aid an already existing cause. There are acute and chronic causes.

Acute.—It may be induced *acutely*, though this is rather rare and sometimes fatal. In advanced cardiac disease with previous atony the latter is doubtless sometimes the final direct cause of sudden death. German students have it at times after severe bouts of beer drinking. Dietetic errors from mechanical causes exert most influence. The overloaded stomach may drag upon the duodenum and cause kinking and occlusion. Hasty eating and the eating of indigestible foods favor such atony, especially in children and after prolonged illnesses, in anæmia, and in various forms of dyspepsia. This is usually temporary and fairly common, and may be mistaken for acute gastritis. It is not due to spasm of the pylorus, as some think, for this orifice is often found open in such cases, and bile has frequently been present in the organ. Neither is there evidence of gastritis, neurosis, or fermentation.

Chronic.—The main causes are frequent heavy meals, hasty eating, especially of vegetables; drinking much fluid frequently. In this way the forced milk cures are sometimes responsible for prolonged atonic conditions of the stomach. So, too, beer and gaseous fluids may induce the same condition.

Pathological Anatomy.—Simple slight atony shows no obvious pathological changes. When gastrectasis exists there may be partial dilatation, *e.g.*, a diverticulum, or general idiopathic dilatation. The lowest point is first involved—the fundus and greater curvature. The muscle is thinned and atrophied, and if the condition has lasted long enough there may be fatty degeneration. Sometimes the wall is compensatorily thickened. Displacement of abdominal viscera may be present.

Symptoms.—These depend on the degree.

Simple Atony.—In *mild atony* there may be no symptoms, or very indefinite ones, with lassitude and heaviness, or a sense of pressure and fulness after meals; perhaps flatulence, with or without a tasting of food taken previously. *This is the commonest of all forms of so-called dyspepsia*. The symptoms are at first present only after the chief meal; later, after each meal. The appetite varies; it is good before the meal, but easily appeased, and there may be cardialgia, and even cramp-like movements (peristalsis), without pyloric obstruction. In such cases there is usually increased secretion of HCl, or of the total gastric juice. There is usually increased thirst owing to the non-propulsion onward of the water, and thus less is absorbed (water is not absorbed by the stomach).

Dizziness, headache, depression of spirits, stupidity, physical languor, and deafness are not infrequent; they are doubtless due to the abnormal dryness of the tissues, to auto-intoxication, and to inanition. The patient may complain of insomnia, especially if hypersecretion is also present. Circulatory disturbances with palpitation or intermittency, also urticaria and erythema, may be superadded. Cold extremities are complained of, and if the disorder is prolonged the patient often looks sallow and his features drawn.

Vomiting.—There is nausea, and even in mild cases sometimes vomiting, though slight and intermittent and at long intervals.

Intestinal symptoms may supervene, with pain, diarrhœa, and mucous stools. Unless there are complications or faulty dieting, the general health and strength are maintained.

Objective Signs.—These depend also on the degree of the atony. The food may be merely stagnant or it may be retained.

Inspection usually shows nothing, or at most slight distention or prominence of the epigastric region.

Palpation often gives a peculiar sense of *even resistance*—flabby, however, rather than tense.

Percussion enables us sometimes to find a somewhat increased gastric area. This increase pertains chiefly to the fundus, which pushes up the diaphragm and gives great increased resonance up to the fourth rib and backward to the posterior axillary line. Or we may find succussion, seven hours after a good meal or two hours after a large tumbler of water. Succussion soon after a meal, obtained in persons who do not complain of indigestion, is suggestive of some atony. We may find dulness at the left parasternal line (on a level with the navel), obtained in the sitting posture, and altering when the recumbent position is adopted. In an atonic stomach percussion areas alter greatly within a very short time.

These methods are all, however, more or less unreliable. *Insufflation* by means of the Higginson's bulb syringe, or *inflation* with CO_2, are better means, and enable us to note the site of the lesser curvature, and to decide on the presence or absence of gastroptosis. *Auscultatory percussion* is unsatisfactory and not to be relied on. Of real importance is the breakfast test, as a preliminary examination. In great stagnation of food this should show the presence, say, of more than 100 c.c. of contents. Another valuable test for the motor power should be employed, viz., an examination of the state of the stomach in the early morning before breakfast. Should this reveal gastric contents there is retention of food—*i.e.*, marked gastrectasis.

Motor Insufficiency with Retention.—(Synonyms: Gastrectasis [Idiopathic Dilatation], Myasthenia Gastrica with Retention.) This is the severer form of motor insufficiency. To mere atony is added fermentation and retention; there is no interval of gastric repose.

Inspection.—The stomach is found to be flabby and much enlarged; the greater curvature may be as far down as the pubis. When patients have thin and relaxed abdominal walls the outline may be easily seen. (Unless ptosis is present the lesser curvature remains high in the epigastrium.) In uncomplicated cases the prominence of the stomach is above the umbilicus, in contradistinction to the prominent swelling of gastroptosis, which is situated lower down.

Inflation with tartaric acid and sodium bicarbonate, or *insufflation* with a stomach tube or Higginson's syringe, will readily reveal the size and situation. *Succussion* will be present in the early morning, and can often be produced at will if the patient suddenly depresses the diaphragm. Sometimes one can feel the gas going through the pyloric orifice, and it may also be heard on *auscultation.*

Percussion gives a deep tympany over the stomach. When fluid is present a dulness may be obtained in the lower part of the gastric area when the patient stands, and this will alter when he assumes a recumbent position. As a means of diagnosis for motor insufficiency this test has but a minor importance.

Fermentation is common, as there are many bacteria present, there are also pyrosis, distention, and vomiting. Vomiting is the rule, and affords great relief; it is characteristic in the following particulars: It is often explosive, but the stomach is by no means fully emptied by the emesis. Periodical recurrences are the rule, and days will often intervene between two attacks. The onset may occur some hours after eating, sometimes showing food that has been retained in the stomach for twenty-four hours or longer. The vomitus is copious; it may amount to one quart or more. It is bitter; usually it has a putrefactive or rancid odor, and is acid in reaction, from the presence of organic acids. Hydrochloric acid may be absent, however, or diminished, normal in quantity or increased, according to the underlying condition. Three layers are apt to form: the lowest containing more or less partially digested solids; the middle layer containing turbid fluid; and the uppermost is foamy, with perhaps some undigested foodstuffs, etc.

Microscopically, there are shreds of mucus, yeast cells, especially if HCl be present, and many putrefactive bacteria. Hydrogen sulphide occurs with benign obstruction chiefly, and marsh gas is not uncommon. The foodstuffs will show different degrees of digestion, according to the presence of HCl, etc. Starch is usually abundantly present, and the granules may still manifest their peculiar characters; the iodine test is also available. There are crystals of fatty acids, epithelial cells, and yeast cells, and sometimes blood cells or pigment. Sarcinæ as well as the various bacteria abound.

General Signs: The *nutrition* suffers proportionately to the degree of dilatation, especially when the secretions are diminished. The tissues become dry, especially the skin. Emaciation may be great on account of the intestines failing to do their part in digesting food which comes to them so badly prepared. The temperature is subnormal, though temporary fever may occur from an associated gastritis.

Constipation results from atony of the bowel, and dry, hard scybala are passed. There is rarely diarrhœa. Sometimes mucous colitis develops. The appetite is worse, and there is more mental depression and more insomnia than in a mild case. The urine is diminished according to the degree of the gastrectasis. It is more concentrated and has a higher specific gravity. The phosphates are increased, and the alkalinity will be marked if there be a hyperchlorhydria. The chlorides are diminished. Sometimes there are albuminuria, acetonuria, and diacetic acid.

The *heart* may be rapid and irregular, owing to the pressure of the distended stomach on the thoracic organs. Sometimes there is bradycardia, though the reasons for this are ill understood. *Dyspnœa* may occur; it should not be confounded with asthma. It is often due to tympanites; hence its temporary duration.

Neuroses of various kinds develop, and especially hypochondriasis. *Tetany* is not rare, and may be present when cases run a severe course. In two patients I have seen death result during a time when dilatation and tetany were combined and no other grave condition was present. Epileptic seizures sometimes occur.

Diagnosis.—The easiest method is by a test meal and an examination of the quantity which remains at a given time. Thus, one hour after a test breakfast there should be not more than 75–100 c.c. of contents left; anything more implies a motor insufficiency. To diagnose the degree of insufficiency one may take three steps:

1. Examination after a test breakfast: If less than 75 c.c. is extracted, the motor power is normal; if the quantity extracted is larger, proceed to the second step:

2. Examination seven hours after a dinner: If no food remains, the motor insufficiency is of the nature of a simple atony; if food still is found, one proceeds to a third and final examination, viz.:

3. Examination of the stomach in the early morning before breakfast: If the stomach be empty there is merely stagnation; if, on the other hand, food be present, the patient is suffering from the third and severest degree of motor insufficiency, *i.e.*, retention, which is equivalent to a gastrectasis.

In the *differential diagnosis* one must exclude:

1. Megalogastria, *i.e.*, a congenitally large stomach (whose motor power is normal).

2. Chronic hypersecretion, in which fluid (gastric

juice) may be found in the stomach in the early morning. This may be decided by careful lavage on the previous evening, when, if mere dilatation is present, little or no fluid will be found in the morning; whereas if supersecretion exists, juice may be removed at that time.

3. Gastroptosis. Sometimes dilatation exists with this condition. The differential point is the determination of the situation of the lesser curvature.

4. Neurasthenia. In this condition the symptoms are usually out of all proportion to the amount of retained food. Solids, too, cause more trouble than liquids in neurasthenia, while the reverse holds in gastrectasis.

5. Gastritis, pure and simple, has no motor insufficiency. The stomach is of normal size and there is mucus.

6. It is of the greatest importance to decide whether the insufficiency is idiopathic or due to an obstruction at the pylorus. The following table will assist the diagnosis:

	Atonic motor insufficiency.	Obstructive motor insufficiency.
History	None other than dietetic excesses.	Previous gall-stones, ulcer, carcinoma, etc.
Course	Slow	Rapid.
Emaciation	Slow	Rapid.
Pain	Insignificant	Is a marked feature.
Contents	A dyspepsia of liquids mainly.	Preëminently solid contents.
Peristalsis	Little or none	Much present and easily excited; the wall is hypertrophic and peristalsis may be visible and palpable.
Dilatation	Usually moderate	Extreme.
Vomiting	Infrequent, copious, liquid, incomplete, less painful.	Frequent, copious, thick, and with much solids, complete, painful; may show blood and pieces of mucosa.
Tumor	None	Present.
Lavage	Quick inflow, slower outflow.	Slower entrance, sometimes quick exit of fluids, expression of fluids easier.
Therapeutic tests.	Improvement decided with lavage.	Progressively worse in spite of lavage.

There should be no difficulty in differentiating gastrectasis from conditions such as ovarian cyst or other abdominal tumor, ascites, distended urinary bladder, pregnancy, though such difficulties are said to have occurred.

Prognosis depends upon the cause and the chance of its removal. The concurrent presence of gastritis or of intestinal disease is unfavorable. Moderate atony is easily curable, by a careful regulation of the diet. Acute cases usually recover; rarely they die. Chronic cases depend upon the degree of insufficiency. If no obstruction exists, the conditions are more favorable. The earlier the treatment is instituted, the better the prognosis. Surgery may often relieve what medicinal treatment has failed to accomplish, and a gastro-enterostomy may restore even the most advanced kind of benign motor insufficiency.

Treatment.—Prophylaxis consists in the taking of nutritious, non-voluminous food (*i.e.*, concentrated), and in advance of those causes mentioned above. The diagnosis of the condition in its early stage is of paramount importance.

Treatment is based on the etiology in regard to food and methods of eating and drinking; it must also have reference to the constitution of the patient and to the fact whether the weakness has followed some general disease like typhoid fever, tuberculosis, etc. In the latter condition, especially, atony is common, and the greatest care is required to prevent the condition from becoming chronic and intractable. Stagnation must be prevented and weakened motor power restored. For this reason no further strain must be placed on the muscular wall of the stomach. The rules and regulations concern mainly, (1) dietetic, and (2) mechanical measures (lavage, electricity, massage, baths, bandages)

Diet: Small amounts taken at short intervals will be better than three large meals during the day. The food should not consist too largely of fluids, as motor insufficiency is essentially a dyspepsia of fluids. For this reason food may be given chiefly in the form of soup, and made up of nutritious constituents in small bulk. The passage of fluids into the intestine is delayed if too much solid food be simultaneously taken. Water alone goes through fairly easily if not in excess. *Multum in parvo* is the guide (*i.e.*, concentrated non bulky nourishment). Milk is therefore good, and one may add some fine cereals to the milk—*e.g.*, barley, tapioca, rice, etc. Bouillon with egg is also a form of concentrated nourishment. The diet should depend, however, to no small extent on the condition of the secretions.

When hydrochloric acid is deficient: Fluid food and soup-like fluids are preferable to dry diet; they should be taken in small amount and frequently. If meats be taken, they should be white meats, or others hashed finely, or fish. Vegetables should be finely divided. Milk is often well borne with cereals, or with nutrose of plasmon. Lactoglobulin is also an excellent preparation.

When hydrochloric acid is increased: Solids are better, especially proteid foods, like meat; starches must be limited; butter is the only safe fat to employ.

In extreme gastrectasis feeding by the mouth may be so insufficient that nutrient enemata will be necessary. In any case water enemata may be used twice daily, even if the condition of dilatation be only moderate. One pint of water with half a teaspoonful of salt may be injected twice daily, or broths, when more nourishment is required, and to this an egg may be added. Alcohols and sugars should be avoided because their absorption induces an extra flow of water into the stomach.

Rest after meals is essential. Exercise at such times tends to injure the muscular coat of the stomach.

Mechanical Measures: Lavage is indispensable in the medical treatment of motor insufficiency if it be at all marked. In the mild cases this may not be required, though it often affords great relief, and is not merely a symptomatic treatment, but even curative, *i.e.*, in the early cases. As a rule, however, early mild cases merely require strict attention to diet and daily regimen to effect a cure. One must judge according to the individual case how much lavage is necessary in severer cases. Moderately severe cases require lavage, as delayed food leads to decomposition and hinders repair.

If food remains in the stomach even till early morning, lavage may be required twice daily: (1) before breakfast, and (2) before the evening meal. The essential is that the lavage be thorough, and that the return flow of water be finally quite clear. It may be necessary to wash out the stomach with the patient in various positions, standing and lying down. Much time and patience may be needed, and often an hour is required before the water returns perfectly clear. The method is similar to that described under "Methods of Examination," on p. 490.

How long should one keep up lavage? This must depend on the remains in the stomach. It should be done daily till we are sure that digestion is not delayed over night. Mere warm water suffices, unless there is great fermentation, and one may then employ salicylic acid (two per mille) or boracic acid in a two per-cent. solution.

Electricity, while often used in vain, is certainly of benefit sometimes, notwithstanding the contrary evidence of experiments upon dogs. Faradism over the stomach, with large electrodes, has a stimulating effect which benefits digestion, either because of its general effect or through the local stimulus to the abdominal wall. There is no advantage to be gained by intrafaradization.

Massage is beneficial in a general way, but it must be employed systematically, and over a sufficient period of time. It is not supposed to be of direct benefit to the muscle of the stomach.

Hydrotherapy is of the greatest benefit, in fact, apart from lavage there is no treatment which compares with it. Cold douches daily with proper friction afterward are most commendable.

Bandages of a supporting nature, or proper-fitting corsets which support from the pelvis, are useful; such corsets are constricted about the hips, but are loose about the epigastrium and lower part of the thorax, thus affording room for breathing, and not allowing the stomach to be without support from below.

Medicinal Treatment.—*Strychnine* is probably the most suitable of all drugs, and may be given in moderate doses after meals. Condurango bark has been recommended in those cases in which the appetite is deficient. It may be given in doses of fifteen to twenty drops of the fluid extract, or may be prepared as a decoction with the addition, afterward, of HCl. If there are signs of supersecretion, atropine may give relief.

For *constipation* purgatives are to be avoided where possible. Cascara and colocynth may be recommended. Massage, proper exercise, and occasional injections of water and oil may not only excite peristalsis but soften the stools. Two per week are sufficient. But few saline waters are useful here. The Carlsbad (Sprudel) are the best of all the salts.

For *vomiting*, diet and lavage should suffice; or if they do not, then nutrient enemata may be employed. Should the symptoms still persist and if they are not due to mere irritability, surgical intervention may be recommended.

For the *thirst*, a Dover's powder, gr. iv., will often be of service.

Surgical treatment in dilatation of the stomach is indicated in: 1. Acute cases in which medical treatment is contraindicated or useless, *e.g.*, twisted duodenum.

2. Idiopathic dilatation (atrophic or atonic form): (*a*) When the medical treatment (dietetic, mechanical, etc.), though beneficial, must be continuous and cannot be properly carried on; or (*b*) when these means fail to relieve sufficiently. The weight of the patient under treatment and the strength and the amount of urine serve as good criteria.

It is well not to wait too long, lest the enfeebled condition may make operation more difficult to withstand.

3. Stenosis of the pylorus (*vide infra*).

The *objects* desired are: To remove the cause of the insufficiency and gastrectasis; to remove the consequences of insufficiency and gastrectasis, *i.e.*, stagnation and retention, and thus give readier transport of food to the intestines.

Patients must realize that with gastrectasis they cannot with benefit carry on the usual routine of living, but that special care is absolutely essential.

Kind of Operation: Gastro-enterostomy, as being simplest and most rational, is by far the best, even when stasis exists. Of this, *vide infra*.

Bircher's operation, to diminish the size of the stomach, affords no benefit and has many disadvantages.

IV. HYPERCHLORHYDRIA.

Definition.—Increased secretion of the hydrochloric acid with the gastric juice during digestion. This is to be distinguished from hypersecretion in which the gastric juice is secreted in excess, not only during digestion, but also at any period of the day or night. It is a symptom rather than a disease *sui generis*, and occurs as a neurosis purely or as a reflex irritation from organic disease of the stomach itself or of other organs (pyloric stenosis from cicatrized ulcer, cholelithiasis, etc.).

Etiology.—This is a very common affection, occurring in young adults rather than in old people, and equally in both sexes.

Among the causes which have direct relation to the disease are chlorosis, neurasthenia, melancholia, psychical disturbances, generally worries and excitements; dietetic errors (eating too quickly or at irregular intervals, especially food which is irritating, *e.g.*, too cold or too hot food, spices, coffee, alcohol). The condition is common in students and overworked business men (stock-brokers). It frequently accompanies ulcer of the stomach, excessive use of tobacco, renal calculi, cholelithiasis, etc., and is often, too, associated with biliary affections and migraine.

Symptoms (in pure hyperchlorhydria with normal motor functions).—The symptoms occur always during digestion, either after each meal or mostly a few hours after the chief meal of the day. Inasmuch as the symptoms arise coincidently with the appearance of the free HCl, their time of onset will depend on the size of the meal (*i.e.*, on the amount of the stimulus). The symptoms bear no ratio to the amount of HCl secreted. There are in pure cases usually a gradually increasing uneasiness, discomfort in the epigastrium, with acid eructations, and heart-burn. About the same time pain appears, which may be slight or severe or of a burning character, and perhaps followed by water-brash or, more rarely, actual vomiting. As a rule the ingestion of food, especially albuminous food, or alkaline drinks, affords temporary relief, while vegetarians find but little comfort under similar circumstances. Headache and dizziness may be present, but all the symptoms disappear as the stomach becomes empty. The appetite is usually good, often voracious (*Heiss-hunger*), and there may be great thirst. Constipation is frequent.

These patients, as a rule, have comfortable nights, and maintain good general health and nutrition.

The *objective* signs present are chiefly a diffusely tender epigastrium, especially during digestion, slight enlargement of the stomach upon inflation, while a test meal reveals a normal motor power, well-digested albumins, and less digested starches. The total acidity is variably increased, the increase being due to HCl. The contents may be rich in ferments, and no bacteria of importance are evident.

Course.—The symptoms may come and go irregularly or periodically; sometimes after certain kinds of food, or sometimes only after psychical or other causes, and in spite of a proper diet. Sometimes there is no pain at any time, even with great hyperacidity, and Riegel is evidently justified in insisting on an examination of the contents to establish a diagnosis.

Cases last for a variable period, most often with remissions and exacerbations, and a cure in aggravated cases is effected only when the cause is removed. In other cases symptomatic treatment alone is of use, and the underlying condition (*e.g.*, tabes dorsalis) keeps up the trouble persistently.

All grades of the condition may occur, from slight temporary attacks of hyperchlorhydria to the advanced condition of chronic hypersecretion.

Prognosis.—The prognosis is good if the condition be uncomplicated. Even after relief has been afforded, however, recurrences are very frequent.

Diagnosis.—The *subjective symptoms* often suffice for a diagnosis. Thus, for example, the pains coming on at definite periods after meals, the relief afforded by certain foods, the good appetite and preserved nutrition, are all important. An accurate diagnosis, however, depends on a chemical examination of the contents and the finding of excessive secretion of free HCl. The presence of free HCl, shown by a qualitative test, and the finding of a total acidity of 70 by the burette after a test breakfast, or of 80 after a test lunch (Germain Sée), indicate a hyperchlorhydria. The excess may double that amount.

One must exclude ulcers of the stomach, gall-stones, and Reichmann's disease (chronic hypersecretion).

The *morbid anatomy* is practically *nil* in pure cases.

The complications are hypersecretion, dilatation, and ptosis.

Treatment.—The daily regimen is of paramount importance. The daily life should be regulated and cares avoided where possible. Proper exercise, especially riding and the like, and a cold bath every morning, are to be advised. Patients should rest after meals.

Medicinally, sodium bicarbonate or magnesia usta in hot water taken half an hour before the pain is expected, usually prevents attacks.

Diet List: Food should be eaten at regular intervals, and slowly, and should be well masticated, and it should not be too hot or too cold. One should avoid anything which stimulates secretion of HCl, *e.g.*, coarse, insoluble foods like cabbage, turnips, celery, carrots, nuts, fruit cores, etc.; too much fatty food and too much sweets; sharp spices, *e.g.*, pepper, mustard, vinegar and other acid foods, horseradish, rich salads, and very salty dishes. Avoid also coffee, beer, and strong alcoholics.

For beverages one may take Apollinaris, seltzer, Vichy, soda waters, etc., with a little mild wine or milk.

Of proteid food one recommends eggs, fish, meats—veal, beef, mutton—and limits starchy foods, which should be well divided up and combined with proteids; also dextrinized forms, *e.g.*, toast or, as soup, oatmeal gruel. Potatoes must be mashed, and sugar should be taken in solutions if no atony exists.

Sample Dietary: 1. Early breakfast: 7–8 A.M., weak tea, milk, or cocoa, dry toast with butter.

2. Late breakfast: 10 A.M., roast meat or chicken, or eggs, toast, and weak tea.

3. Dinner: 1 P.M., soup with egg; roast meat, chicken, or fish; asparagus tops; a little mashed potatoes; omelette soufflée; Vichy or Apollinaris with hock or claret.

4. Tea: 5 P.M., tea and biscuits.

5. Supper: 7–9 P.M., cold meat sandwich, or a hard-boiled egg at bedtime, cocoa or milk, or a little honey instead, Swiss or Dutch cheese and crackers.

If the appetite is good, meals Nos. 1 and 4 may then be omitted, and but three meals daily taken; if the appetite is poor, four or five small meals should be taken daily.

Alkalies are taken as directed, and among the most useful are the Sprudel salts for constipation, one teaspoonful being taken in hot water before breakfast.

V. HYPERSECRETION.

(Synonyms: Continuous Secretion, Reichmann's Disease, Gastro-succorrhœa Continua Chronica).

Definition.—An excessive secretion of gastric juice, usually hyperacid, occurring not only after meals, but during fasting also. This is more often a symptom than an idiopathic disease, and occurs probably oftener than is realized in benign pyloric stenosis and certain forms of chronic gastritis; also in gastric neuroses. It is at times paroxysmal and recurrent (the intermittent form), and has been called gastroxynsis (Rossbach) and intermittent hypersecretion (Riegel). Patients thus afflicted are usually quite well in the intervals. To the more continuous form the term Reichmann's disease has been applied. Normally there should not be more than 20 c.c. of gastric juice at any time when the stomach is without food, and usually there is only from 1 to 10 c.c.

Etiology.—Young nervous men are most often affected. Dietetic excesses in quality and quantity, excitement and gastric motor insufficiency, are the chief direct causes.

Symptoms.—These vary according to the degree, and come on insidiously, often after long-standing dyspeptic symptoms. Early signs are restlessness, discomfort, and finally pain two to three hours after meals; then perhaps headache, nausea, flatulence, and, after another hour or two, vomiting supervenes, giving temporary relief, or the vomiting may occur after many hours of fasting. The vomitus varies in quantity, is usually fluid, of a low specific gravity, 1.004–1.006, showing free HCl usually in excess, is clear, or turbid green with bile, and bitter to the taste. Sometimes vomiting is absent.

These distressing symptoms come on frequently at night and in the early hours of the morning, disturbing the patient's sleep, a fact which is of considerable importance in the diagnosis. Added to the headache are signs of intestinal indigestion, from an over acid chyme, and constipation. The appetite varies, as also does the sense of thirst. Emaciation and weakness follow, and the patient, if untreated, often develops signs of cachexia.

The degree of these symptoms varies greatly. In some cases they are of short duration, but recurrent at long intervals; at other times several attacks may occur in a single day, or, lastly, the condition may persist and the patient be a chronic sufferer.

Examination of the patient reveals often a sunken abdomen, and perhaps an enlarged and dilated stomach, at times too a gastroptosis. The stomach contents, after a test meal of Riegel, show marked digestion of albumens, and relatively little alteration in the starches.

Diagnosis.—If the tube is passed in the early morning before food has been taken, a varying but excessive quantity of gastric juice (usually hyperacid) may be removed—an indication that secretion persists even without the stimulus of food. This is the *crucial feature of the diagnosis*, though to avoid error it is important thoroughly to wash out the stomach on the evening previous to such an examination, inasmuch as there may be a concomitant motor insufficiency (which should of course be thus excluded).

One must exclude ulcer of the stomach and duodenum, scarred ulcer, hypertrophic stenosis, and other benign obstructions at the pylorus, and finally organic cerebral and spinal-cord lesions.

Course and Prognosis.—The course depends upon the possibility of removing the cause. Intermittent cases are usually easy to relieve. These idiopathic cases may, if mild, be readily cured by treatment. The severe ones may last for years, and then usually result in a complicating dilatation. In such cases the symptoms become aggravated and patients suffer much, especially at night. Death does not occur from the simple idiopathic condition, but in complicated cases it may follow from marasmus or fatal hemorrhage from an ulcer.

The prognosis is uncertain. Recurrences of the mild condition are common; complicated cases are especially difficult to cure. Operation (gastro-enterostomy) relieves cases with marked dilatation and motor insufficiency.

Treatment.—Treatment must be directed to prevent stimulation of HCl, and yet to afford enough nutrition without overburdening the stomach. Hence those substances should be taken and avoided as in cases of hyperacidity (*vide antea*). Special care must be taken in the diet to avoid the onset of motor insufficiency, or, if it is already present, to prevent its increase. Hence meals must be nourishing and in small volume. Fluids and starches must be limited, the latter finely divided, and given when the stomach is freest from HCl. In most cases it is well to give food five or six times daily in small quantities each time.

Lavage is useful in most cases, and is essential where atony is marked. It is best carried out, as Riegel suggests, before the evening meal. Pains are thus relieved and digestion made more easy. Alkalies, however, often suffice to relieve the pain, and are given before digestion reaches its height. If no atony exists, one may give alkaline waters with benefit; or one may use powdered calcined magnesium and sodium bicarbonate. Atropine sometimes gives remarkable relief, while others find in Dover's powders immense benefit.

Gastro-enterostomy is of value only where marked motor insufficiency is present, and in such cases it is useful, not only in aiding digestion, but also in relieving the pains and discomfort of faulty digestion. The excessive secretion need not thereby cease. It is doubtful if the direct application of galvanism to the stomach has more than a normal effect on the condition.

Hygienic conditions and daily regimen are to be provided for, as in cases of hyperacidity.

VI. NEUROSES OF THE STOMACH.

To group the neuroses of the stomach one may well follow the German method, according to which neuroses are: motor, secretory, or sensory. Even more than in other classifications these divisions overlap, neuroses of different groups frequently occurring in one patient. Leube even puts into one group those cases which show a combination of two or more of the above divisions. These he speaks of under "Nervous Dyspepsia," in which chapter he shows that the sensory disturbances predominate.

And one is reminded here that no irritation or disturbance can be felt by the stomach or transferred to the centres, or *vice versa*, except by means of the nervous system. Every gastric trouble then is, strictly speaking, largely nervous. We now know, too, that for the secretion of gastric juice the undisturbed function of the vagi is essential, the mere mechanical irritation of the gastric mucous membrane not always sufficing, while suitable stimulation of the mouth or gullet, or even some of the organs of special sense, will call forth the secretion. The circulation in the stomach, too, as well as the secretion, and the muscular tone are controlled, for the most part, directly by the nervous system.

The causes of gastric neuroses in general are those which so incoördinate the nervous system by afferent impulses, or so exhaust it by afferent energy, that it is unable to supply that work which is one of the essentials to gastric function. The exciting causes are frequently illustrated by persons eating large meals while in a condition of general exhaustion. A physician's eating heartily immediately after a worrying night's work in obstetrics, a commercial man's taking an unusually large meal after an anxious day, or an athlete's heavy meal after his first practice, are familiar examples. Such indiscretions are followed by distress and burning sensations, restlessness, at best diarrhœa and flatulence, leading to a "bilious" attack next day. Atony is a frequent accompaniment.

MOTOR NEUROSES.—*Peristaltic Unrest* (Kussmaul).—Strong, sometimes visible and palpable movements, not due to stenosis or ptosis, are rare. They do, however, occasionally occur as a result of increased excitability of the peripheral nerve apparatus—that is, as a motor neurosis. This may be observed even in the early morning when the stomach is empty, but it is usually worse after a meal, and sometimes produces movements even in the small intestine. This neurosis may be temporary or permanent, and it is frequently observed with ptosis. There are, of course, all grades between peristaltic unrest and that condition in which digestive movements are abnormally hastened (hyperkinesis). The patient complains of a sense of unrest, movements in the stomach, and a drawing-together of the abdominal organs which leave him no peace, although there is no pain. There are usually no secretory or other changes.

Anorexia, nausea and vomiting, and insomnia may accompany the other complaints. On inspection of the abdomen one sees the peristaltic movements. Palpation and chemical examination should exclude the presence of any organic disease.

Diagnosis. Diagnosis is easy if there is ptosis, which enables one to watch the stomach, including the pylorus, satisfactorily. If there are only subjective symptoms, one must exclude mainly stenosis and dilatation. It is well to remember that the fact of a patient being neurotic is not *per se* sufficient to insure the exclusion of organic disease!

Course and Prognosis.—This depends on finding and removing the cause.

Treatment. Remove the nervous cause if possible. General hydrotherapy may be ordered. The diet is to be non-irritating, and the evening meal light. Compresses or galvanism may be tried, and small doses of bromide of potassium.

Hyperkinesis.—This is an increased motor activity, the stomach emptying itself more quickly than normal, and is a pure neurosis. In its pure form it is a neurosis without secretory changes; but nearly always there is, preceding the condition, an increased production of hydrochloric acid. For the diagnosis one must carefully examine the stomach contents and the motor power.

Spasm of the pylorus is usually secondary to ulcer, more rarely to cancer (even if lactic acid is present in increased quantity), to gastritis, and to secretory disturbances. It is also due to dietetic errors, especially extremes of temperature of the food, or mechanical excess. According to Osler, its existence as a true neurosis is doubtful. Clinically, one hears of sharp pain and observes a prompt peristalsis, perhaps vomiting, or flatulence and distention, and a sudden relief, which is suggestive. One can sometimes feel the hard pylorus. Inflation is easy, but evacuation is prolonged. Intermittent stagnation and retention turn one's mind to this condition. Pyloric spasm, when secondary to a continuous hyperacidity, may lead to dilatation and its sequelæ.

Etiology. In searching for the cause one looks for a neurotic constitution, with worry and anxiety. The disease has been caused by biliary colic and acute enteritis.

Treatment. This is general and dietetic, according to needs. Galvanism and bromides may be of slight service.

Spasm of the Cardia.—This is a spasm of the circular fibres of the cardia with or without pain, and of variable duration. Food and secretions are retained in the œsophagus, above the spasm; gases remain below the spasm, in the stomach.

Etiology. Spasm of the cardia results from: 1. Irritants entering the œsophagus, *e.g.*: (*a*) the stomach tube, (*b*) irritant poisons, (*c*) food which has been too quickly swallowed, and (*d*) too hot or too cold food. 2. Inflammations. 3. Ulcer. 4. Cancer. 5. Hyperchlorhydria. 6. Tympanitic stomach. 7. Simple spasm. This last is rare, though it may occur at any age as a result of hysteria in neurotic individuals, and has been met in air swallowers. It is caused by tobacco, by arteriosclerosis, by tetanus, and by diverticula.

Spasm of the cardia may last for a long time, or may be of short duration and recurrent. Each attack is sudden, with painful contraction perhaps, and a sense of pressure and pain. One feels as if the food were held back about the stricture or regurgitated. In a few there is distress, with retching and vain attempts to bring up food, or actual vomiting may occur. The patient makes voluntary efforts to compress the thorax, or holds his breath, or drinks fluids in order to force the food through into the stomach. There is dysphagia or delay in swallowing, and sounds of deglutition are less distinctly heard or long delayed. In passing the tube one meets with a resistance which can be overcome.

Einhorn believes that the recurrent filling of the lower area of the œsophagus with food and taking water to force down every few mouthfuls lead to dilatation of the œsophagus. Riegel doubts this, rather regarding the dilatation, more especially the diverticula, as the result of concurrent inflammation. The dilatation may be symmetrical, pouched, or diverticular. As soon as dilatation exists dysphagia becomes constant, and there is more dyspnœa, with palpitation, contributed to by fermentation and putrefaction. A dilated œsophagus may hold more than one pint.

Differential Diagnosis. One must exclude the various non-spasmodic obstructions, such as tumors causing external pressure, or, again, organic stricture from any cause.

Treatment. Mostly prophylactic. In general the food should be of a proper temperature, slowly eaten and well chewed. If a sensitive œsophagus seems to be the cause, pass thick sounds, which gradually relieve, unless erosions are present, in which case only very soft food is allowed. As a rule in such conditions local treatment is over-treatment. It has been recommended for chronic cases to give food of the consistence of soup, to direct the patient to press the food past the stricture, to stretch with sounds, and to perform lavage daily!

Nervous Eructations.—These occur independently of meals and from nervous causes; flatulence being generally present. They may be audible, and may last for hours or days. They depend on hysteria or neurasthenia, while children produce them in mimicry. The air which escapes is not always gas generated in the stomach; it may be air which has been aspirated or swallowed chiefly the latter. The discharge is partly reflex, but mainly voluntary, the swallowing of air being followed by induced spasm of the pharynx. The paroxysm has no constant relation to food in any way or at any time. Emotions, however, are closely related to the eructations. Belching may or may not relieve. Sometimes the eructations are periodical, while at other times they are sudden and unexpected, being noisy and most embarrassing. They cease at night generally.

Diagnosis. The problem is to distinguish between the nervous and the fermentative origins. One may examine the stomach contents, though the general aspect of the case is of more significance.

Course and Duration. These depend largely on the success or failure of suggestive therapy and general treatment of the nervous system.

The *treatment* is mostly psychic, though bromides will relieve, temporarily at least. Tonics, change of climate, and hydrotherapy have done good. One can stimulate self-control by advising great care in combating the trouble.

Nervous Vomiting.—The following varieties are not included:

Cerebral Vomiting.—(*a*). Organic disease of brain, circulatory changes, concussion, tumor.

(*b*) Intoxication, *e.g.*, opium, chloroform, ether, tobacco, uræmia, cholæmia.

(*c*) Psychical, through the special senses—*e.g.*, sight of disgusting objects, or waves on the ocean.

(*d*) Reflex, due to anatomical changes, *e.g.*, neuritis, vagus affections (in mouth or in stomach); peritonitis, ileus, appendicitis, ovarian disease, pregnancy, etc.; liver disease, kidney disease (stone), worms, constipation, etc.

Spinal Vomiting.—Tabetic crises, characterized by sudden pain in the abdomen, with agonizing vomiting of food, then of mucus, often with hyperchlorhydria. The crisis may last two or three days, and in the interval the stomach is normal. Such a crisis comes either early or late in the disease and may persist. It is sometimes seen, too, in general paresis, multiple sclerosis, and myelitis.

True nervous vomiting is hysterical and therefore far more frequent in the female sex than in the male. It may come with or without other symptoms, coming easily with no preceding vomiting, and not always after a meal. In some cases it is produced only when solids have been eaten; in others, when fluids have been taken. In some patients it occurs only in the recumbent position; in others only in the erect posture. The quality of the food seems to make no difference, and there are no other dyspeptic troubles in the interval. It is striking, too, that the nutrition, as a rule, is well maintained, though exceptionally there is emaciation. Psychic influences are strong in its causation. Hæmatemesis rarely accompanies it. As a rule, the general health is unaffected. In its diagnosis one must exclude all anatomical changes and then find a cause. One must exclude, too, hyperchlorhydria, hyperchylia, and tabes.

The *treatment* is suggestive. In severe cases rest in bed with careful experiments in dieting is necessary. Lavage is useless, and one may have to resort to rectal feeding.

Periodical vomiting resembles tabetic crises. It occurs in healthy people independently of any spinal disease, suddenly and without apparent cause, often in the early morning before any food has been taken. Nausea precedes the vomiting, which is violent, and then perhaps malaise, headache, etc., follow. Vomiting begins as soon as food is taken; the vomit is copious, and when all the food has been returned the vomit becomes bilious. Then it ceases, either suddenly as it began or gradually. More food can now be taken and retained, sleep intervenes with recovery until the next attack, which is a close copy of the first. Often there is no pain, but sometimes the patient complains of cramps and of considerable prostration afterward.

Regurgitation.—There is a nervous regurgitation of liquid or solid food, apart from organic disease of the stomach. The ejected material shows no abnormality of smell or of taste and is spit out, or in some patients swallowed again. Relaxation of the cardia is suspected in these cases. In severe cases, with loss of large quantities of chyme, serious inanition has been observed (Einhorn). Intragastric faradization is of doubtful use, and strychnine may be ordered. The patient should be informed of the evils of such a habit, and her self control otherwise stimulated. When a subject of this neurosis faithfully reswallows according to order, it may give place to genuine

Rumination or Merycism.—This implies the regurgitation of food, its remastication and subsequent reswallowing. It is generally acquired through mimicry and may lead to a habit. Einhorn could collect only one hundred and six cases in the literature, and most of them were males. It is repeatedly seen in the insane, while in Montreal hospitals and elsewhere we have found it not uncommon in persons healthy in both mind and body. Like other hysterical manifestations it is influenced by critical events—it having appeared the day after marriage in one case; in another it was cured by marriage. Suggestive treatment has proved the most successful. The patient should be soundly lectured on the vice, for it is among the most disgusting of habits.

Gastroplegia.—Atony of the stomach is familiar as the result of many organic changes in that organ and of general wasting processes. A paresis of functional origin does rarely occur, in the diagnosis of which a very thorough exclusion of other causes must be carried out. The main symptom is marked motor insufficiency. Its main treatment must accordingly be directed along these lines.

Pyloric Incontinence.—This can be recognized by the presence of bile and intestinal juice in the stomach during the fasting hours, though this is not constant. Generally speaking, one is not able to force air through the pylorus during excessive inflation. An incontinent pylorus, however, is apt to prevent prolonged distention of the stomach after inflation, and a test meal is said to leave the stomach sooner than normal.

SECRETORY NEUROSES. — 1. *Hyperchlorhydria and Hypersecretion.* (Vide sections IV. and V.)

Hyposecretion and "Achylia Gastrica."—Under this heading one includes deficient hydrochloric acid, deficient total secretion, and absent secretion. The existence of the latter as a neurosis is doubted by many. Such are secondary to many organic diseases, *e.g.*, cancer, gastritis, amyloid degeneration, profound blood changes, and atrophy. They occur, too, as a neurosis. Complete achylia, it is said, sometimes occurs in tabes. In true achylia due to organic disease one can generally find without much delay definite signs of organic change, whereas in neurotic achylia the mucous membrane is in normal condition. In a case recorded by Einhorn the secretions returned after five years of total achylia gastrica! Subjectively the patient may be in good health and free of symptoms, but if motor insufficiency or intestinal trouble is present there are always symptoms. There are generally various gastric symptoms and mild enteric manifestations, though no characteristic symptom complex whatever. Objectively, one finds, on withdrawing the contents after a test breakfast, that their total bulk is small, and there is very little fluid. The food is unchanged, hydrochloric acid is absent, and the contents are neutral or faintly acid, a total acidity of four and even two having been observed. Lactic acid is absent, or very nearly so; there is no peptone, propeptone, pepsin, or rennet ferment, and no mucus.

The *course* is very protracted, and the *treatment* consists of stimulation by lavage or faradism, preparation of the food to suit the intestines, a large proportion of vegetable food, and medicinally nux vomica with hydrochloric acid.

SENSORY NEUROSES.—*Hyperæsthesia* occurs also with ulcer, hyperchylia, gastritis, chlorosis, arthritis, uræmia, irritating foods, habitual ingestion of narcotic drugs, fasting, and various excesses.

Subjectively there is discomfort immediately after a meal, whether fluid or solid, then a tingling pain throughout digestion (due to contact of food with the mucous membrane). Sometimes there are excessive nausea and vomiting. During gastric repose there is no pain, but generally a sense of emptiness, and perhaps faintness. Pain is induced sometimes by too warm food, or by pressure over the stomach, and often by the tube. The skin of the epigastrium may be tender. Fear of pain leads the patient to take an insufficient quantity of food, and this, with vomiting in severe cases, brings about emaciation. The secretions remain normal.

One must differentiate this neurosis from:

(*a*) Atypical ulcer, in which there is a distinct relation of the pain to the quality of food, to the evolution of the secretion, and to the movements of the body. The differential diagnosis is often difficult, and can often be only surmised from facts in general.

(*b*) Hypersecretion, in which the pain occurs later on, toward the height of digestion—*i.e.*, in which the pain is not related to contact, but to function and to the quality of the food. The effect of albuminous foods in hyperchylia may be to relieve; in hyperæsthesia such foods aggravate the pain.

(*c*) Hypersthenic gastritis; the differential diagnosis is the same as in hyperchylia.

Gastralgia.—Gastralgia is *symptomatic* in ulcer, cancer, gastritis, retention, gastroptosis, and hyperchylia; it is *reflex* in genito-urinary diseases, etc.; it is *central* in tabes, multiple sclerosis, myelitis, and tumors; it is *neuralgic* in neuroses, chlorosis, syphilis, auto-intoxications, and possibly in malaria.

Gastralgia is a pneumogastric neuralgia. It may be mild or severe. The pain is intermittent, *i.e.*, there are intervals of normal painless digestion; it comes suddenly, working up to a paroxysm, being felt first in the epigastrium and then shooting through to the back, with an increase in its severity. It has no relation to functional activity in the stomach, and is not associated with any dyspeptic signs except distention. This pain may last several hours or may persist during two days.

The urine is usually neutral, and on the cessation of the pain large quantities are passed. Sometimes vomiting ends an attack. The stomach contents are normal.

Gastralgia nervosa is to be differentiated from all diseases in which pain occurs at or near the epigastrium, *e.g.*, from intercostal neuralgia and myalgia; from gallstone colic; from intestinal colic; etc. In gall-stone colic the pain may also be felt to the *right* of the twelfth dorsal vertebra. The liver is enlarged and the gall bladder palpable, while there may be jaundice and fever. The colic may be related to the taking of excessive food, as in two cases which I have seen; the differential diagnosis is then often difficult. The stools should be carefully examined.

When, in a case of intestinal colic, the seat of the trouble is in the transverse colon, the diagnosis may be difficult. There may be mere peristaltic pain, or plumbism, simple distention or mucous colitis.

Gastric hyperæsthesia, hypersecretion, and hyperchlorhydria must also be considered in the differential diagnosis, nor should one omit to think of ulcer (gastric or duodenal), pancreatitis, peritonitis, etc.

Treatment. In severe cases a hypodermic of morphine should be promptly administered by the physician. In less severe cases one may try the various gastric sedatives (bismuth, cocaine, chloroform, and silver nitrate). Washing out the stomach freely with hot water, combined with hot fomentations externally, has acted well, though, as a rule, it is an unnecessary procedure. The chief indication is to treat the underlying cause (general condition).

Anorexia Nervosa.—*Definition.* Anorexia nervosa is a term applied to a sudden loss of appetite, developing along nervous channels, and in the absence of organic disease in the stomach. It is thus a pure neurosis, and occurs most commonly as a very prominent symptom in hysteria or neurasthenia, of which it forms the most striking complaint on the part of the digestive system.

Etiology. Various gastric symptoms are very common in neuropathic persons, whether the latter suffer from a slight passing irritability, a profound neurasthenia, or insanity; and this neuropathy should be looked upon as the background and the foundation of the gastric trouble. Anorexia nervosa occurs, too, in perfectly healthy people, after psychical excitement, a fright, or a sudden depression of spirits, as also after a disgusting sight or odor. In such cases the symptom is of short duration, whereas when it is a part of general hysteria it is very obstinate, becoming serious and even dangerous in many individuals. It is particularly common in young females, owing to the great prevalence of hysteria and chlorosis in such persons. Typical examples have been seen in those who abuse morphine, tobacco, or alcohol. In fact, any influence which exhausts the central nervous system may lead to anorexia nervosa, whose etiology is that of the parent disease, hysteria.

Symptoms. The loss of appetite, which is sudden and generally complete, comes on commonly immediately after the ingestion of food; more rarely it occurs several minutes after the first mouthful. The patient comes to table with a good appetite, but on beginning to eat experiences from the first mouthful a sense of satiety and even of fulness and weight in the stomach; her appetite, and, indeed, her ability to swallow, instantly leaving her. For it is more than a mere loss of appetite, and the approach of food brings about contraction of the œsophagus or an obstinate gagging, while food forcibly inserted is returned before it reaches the stomach. In less severe cases the appetite is absurdly capricious, varying quickly from one extreme to the other. When the ability to eat has gone, no suitably chosen food as to quality or quantity can well be taken, for one spoonful of fluid is intolerable. This may be lasting, and, when such is the case, it leads to loss of weight and muscular restlessness, producing muscular atrophy and contractures, so that the patient lies in flexion, and feeding her becomes a very difficult problem. Such are the extreme cases to which Weir Mitchell applied his treatment. Emaciation may be extreme, the very skin becoming dry and wasted. Patients have died from starvation. Osler records the case of a girl who died at forty-nine pounds' weight without any lesions being found after death. A woman under Riegel's care kept on reducing the size of her meals until only from two to four drachms of fluid could be taken; she became bedridden from weakness, and her weight fell to sixty-four pounds. After ten months' careful treatment she was discharged weighing one hundred and thirty-four pounds.

Diagnosis. The diagnosis depends on the history, family tendencies, and the nervous disposition of the patient, and, above all, on the exclusion of all organic disease in the stomach or elsewhere. Therefore a very searching investigation of the stomach and of the entire organism must be carried out. In the absence of any recognizable disease the symptom may depend on a hidden lesion, notably tuberculosis.

Treatment. In treating these cases, any contributory causes (abuse of drugs, excesses, anæmia) must be combated, and a cure depends largely on the personality of the physician and his ability to win and hold the complete confidence of his patient. In all severe cases the only hopeful treatment is the removal of the patient to an institution where her nurses are strangers and where a strict regimen, dietetic and otherwise, can be carried out. In such surroundings sensational cures are sometimes obtained. Rectal feeding and gavage have at times to be tried, and their psychic effect is in some cases successful

"Neurasthenia Gastrica" and "Nervous Dyspepsia."—*Definition.* We have seen above that gastric neuroses are secretory, sensory, or motor. These are, unfortunately, often combined and form what some authors call "nervous dyspepsia," or neurasthenia gastrica. The term "nervous dyspepsia" was first given by Leube to a condition characterized by gastric symptoms referable to the nervous system in the presence of normal digestion —*i.e.*, normal as to its chemistry and duration. Such a condition is generally a sensory neurosis, which, however, is sometimes combined with other neuroses. We, therefore, look upon nervous dyspepsia as a composite neurosis, in which sensory disturbance is always prominent.

Symptoms. The symptoms are a sense of fulness and weight, eructations of gas, nausea, and even vomiting; there may be pain and tenderness (not limited to a small area), also burning, and disturbed appetite. Secondary symptoms are headache, palpitation, insomnia, and moodiness. The symptoms always appear shortly or immediately after taking food, but they do not vary with variations in the quality or quantity of the food, but persist in spite of judicious reductions in the diet. Such symptoms are at times a part of general hysteria or neurasthenia. They occur, too, reflexly from disturbance of other organs, *e.g.*, the female sexual organs, during a heightened general nervous irritability. They probably occur as a result of sexual excess, though in this and other distant disturbances an increased irritability of sensory nerves in the stomach is essential. If this irritability is present, physiological events in the stomach call forth unpleasant symptoms or become painful, leading to abnormal secretion and abnormal motility. The patient may or may not be hysterical, for these neuroses can occur apart from definite hysteria, though a neuropathic constitution is essential. This constitution may be congenital or acquired by such means as excesses, abuse of drugs, chronic malaria, anæmia, etc.

On physical examination of the abdomen one finds no abnormality, not even localized tenderness. The gastric juice, too, is almost always perfectly normal, though rarely it is slightly changed. Motility is generally normal, rarely there is hypermotility, and more rarely atony. Generally there are also perverted sensations in the intestines.

Course. The course is always long, but the condition varies sensationally, especially with the mental state and surroundings of the patient.

Diagnosis. The diagnosis is made only by the general clinical picture, never by any single sign, nor by the examination of the gastric contents. In this condition the pain is not so severe as in hyperacidity. Changes in the secretion or motility at frequent intervals are suggestive, especially when vomiting is absent or infrequent and the tongue clean. Striking variations in the symptoms, synchronously with changes in the humor of the patient, together with excellent nutrition, in spite of severe symptoms, are the most suggestive points. One must not lay too great stress on other functional disturbances, for organic disease in the stomach may coexist with hysteria, and the more conscientiously one examines his patient, the more frequently will he find an organic basis for the symptoms.

The diseases differentiated with greatest difficulty are atypical ulcer, carcinoma, and chronic gastritis. In ulcer, when there is no localized tenderness and no hæmatemesis, one may have some doubt. In ulcer the pain is much more regular in its relation to a meal, and it varies markedly with the quantity and the quality of the food; vomiting is far commoner and the appetite is good, fear alone preventing eating. In ulcer, too, hyperchlorhydria is almost constant, and the symptoms respond more to treatment than is the case in neurasthenia gastrica. In cases of carcinoma, with absent hydrochloric acid as the only sign, one may long be in doubt; one must consider the age, sex, and the course of the disease, and look for constantly absent hydrochloric acid. In chronic gastritis the course is always steadier; there is much mucus, and the symptoms increase or diminish with the diet.

Prognosis. The prognosis is good as to life, but the symptoms are of long duration or frequently recur.

Treatment. One should try to remove all exhausting influences and give his chief attention to the general condition of the patient. The diet is not of prime importance, but should be nourishing and unirritating. A change of scene, as by a trip to the country or by a sea voyage, acts well. Tonics, hydrotherapeutics, massage, and static electricity may be given, mostly for their psychic effect. Obstinate cases can be cured only by the Weir-Mitchell treatment, in which suggestion and the encouraging personality of the physician are important.

VII. GASTRITIS.

ACUTE GASTRITIS.

DEFINITION.—An acute inflammation of the superficial membrane of the stomach with excessive secretion of mucus, desquamation of epithelium, and a resulting disturbance of digestion. The term is often misapplied, and is confused more especially with gastric neurosis, in which there is no evidence whatever of inflammation of the lining membrane of the stomach. The term should be restricted to those cases in which definite evidence exists of a catarrhal or other inflammation of the gastric mucosa, and should not include even those cases of neurosis in which much mucus is secreted in the stomach, and in which there is no cause or symptom otherwise of inflammation. One should exclude, too, the many cases of acute indigestion from temporary indiscretions of diet, etc., and the cases of slight atony, in which there is no reason to suspect an active inflammatory process.

It is true, on the other hand, that in many cases it is impossible to say whether one is dealing with an acute inflammation or with merely an acute non-inflammatory dyspepsia.

ETIOLOGY.—The condition is either primary or secondary.

Primary Acute Gastritis.—The causes of the primary simple gastritis are mainly the following: Food or drink when taken in an irritating form, *e.g.*, too hot or too cold, or if decomposed, or if too spicy, or too bulky and coarse—all these act more especially on an empty stomach.

Alcohol, which is one of the most common causes, induces a very typical form of the disease.

Individual predisposition and sensibility have much to do with the case, and perhaps, too, heredity plays its part. Again, people with impaired vitality—such, for example, as anæmic individuals and those who are convalescing from the specific fevers—are more susceptible. For the same reason tuberculous patients are often susceptible to the disease. Bacteriological invasion is not infrequently a factor in its causation, and more especially is this claimed for the Bacillus coli communis, while in many cases the disease is associated with the parasites of pyæmia, diphtheria, anthrax, thrush, lymphangitis, etc. Animal parasites, again, may be introduced, such, for example, as the Ascarides and the various Tæniæ.

Toxic causes are amongst the most common factors in the production of acute gastritis, though in most instances they produce a more severe form than is here described. Such, for example, are the mineral acids, the alkalies, various salts, alcohol, phosphorus, arsenic, mercuric chloride, calcium chloride, etc.

Externally, heat and cold, when excessive, may induce gastritis, though just why extensive burns on the external surface of the body should produce so frequently catarrhal inflammations of the mucosa is not understood. Foreign bodies when swallowed form another cause (fruit stones, hair, etc.).

Lastly, there seems to be an epidemic form of the disease, the cause being doubtless some micro-organism, though the mode of infection is as yet ill understood.

Secondary acute gastritis frequently develops with the general infectious diseases, such as measles, scarlatina, erysipelas, pneumonia, etc., and may indeed be the primary condition which manifests the early symptoms, and this is especially so with children. In acute nephritis, again, gastritis is a common secondary condition. With diseases of the throat and with putrid bronchitis, gangrene, or other disease of the lung, or in other conditions in which the degenerated tissues are in part introduced into the stomach, a secondary gastritis may readily occur. The disorder, too, is not uncommon with, and as a result of, intestinal disease.

MORBID ANATOMY.—Macroscopically there are a diffuse circumscribed swelling of the mucosa, redness, due either to congestion or to hemorrhage, and an excessive quantity of mucus. Sections under the microscope show partial desquamation of the superficial epithelium, the remaining cells being swollen and cloudy and filled with much mucus. In the glandular epithelium it may be impossible to distinguish between the chief and the parietal cells. All the cells may be more or less cloudy, fatty, or granular and shrunken, the chief cells being those usually most affected. The capillaries are dilated, and in the interstitial tissue one sees collections of small round cells, due to inflammatory infiltration.

SYMPTOMS.—The symptoms may occur with or without fever.

Subjective Symptoms.—There is usually general malaise, perhaps headache and dizziness; the patient complains of anorexia, increased thirst, a sense of pressure and fulness in the epigastrium, eructations of a gas which is either tasteless or bitter; there is a pappy taste in the mouth, and nausea is usually present. In most cases there is some vomiting of a foul, very acid, bitter material, consisting of more or less undigested food remnants and much mucus. There may be bile. Such a vomitus has a very marked acid reaction, though the HCl acidity is usually diminished, and there may even be no free hydrochloric acid; very often the three organic acids—lactic, butyric, and acetic—are found.

If a test breakfast is given after the first violent attack is over, one will find the bread after one hour almost unchanged, very much mucus present, and a greatly diminished secretion of hydrochloric acid.

Objective Symptoms.—These are not specially characteristic; the tongue is usually coated, and it may be indented by the teeth; if fever is present, there may be herpes labialis. There will be some tenderness in the gastric area, and perhaps fulness from distention. The intestines are sometimes involved in a severe case, and there may be constipation or diarrhœa. A more or less subicteroid condition may be added. The pulse is increased in rapidity and is small in volume. The urine is diminished and the specific gravity increased

COURSE.—Sometimes vomiting affords immediate relief; at other times the vomiting and the symptoms are concurrent. Not infrequently involvement of the intestines follows that of the stomach, and then after a preliminary constipation there is more or less persistent diarrhœa for one or more days.

The intensity varies, and in the milder cases there is even no vomiting. On the other hand, in those cases which are somewhat more severe, rigor may be present, with fever and herpes.

DIAGNOSIS.—An obvious cause is usually the important factor, and in addition the vomiting of coarse undigested food after some hours, with much mucus and organic acids, suffices to render the diagnosis easy.

The differential diagnosis concerns gastric ulcer, biliary colic, gastralgia, with increased hydrochloric acid, the onset of some acute infectious disease—more especially typhoid fever and pneumonia—and lastly, the gastric crises of tabes dorsalis. The individual symptoms and the course of the disease usually suffice for a diagnosis.

PROGNOSIS.—The prognosis is good. There may, however, be recurrences in susceptible individuals, which, when they occur frequently, increase the liability to a chronic gastritis with secondary dilatation.

TREATMENT.—*Prophylactic.*—This is of especial importance in children, inasmuch as an improper diet is the frequent cause of gastritis at that age. It is important, therefore, to avoid overloading the stomach, especially with sweets, fruits, cakes, and other foods which cause fermentation and more or less acute dilatation of the stomach. Some authors have laid stress on the importance of avoiding uncooked fruit, which is especially irritating to the stomachs of the young.

Direct Treatment.—The condition often subsides of its own accord without any further interference, and nature, by inducing vomiting and a subsequent anorexia, carries out the two main therapeutic essentials. When vomiting has not been induced, emetics often give relief, though lavage is, perhaps, the more thorough method of treatment. It is specially useful in children, in whom lavage, by means of a catheter or properly devised tube and funnel, gives more rapid relief than any other treatment. It may be necessary to employ lavage with the patient in various postures in order to insure a thorough cleansing of the stomach, and this process should be repeated several times if symptoms of discomfort and distress indicate its use.

If an emetic is desired or necessary, apomorphine is doubtless the best one for the purpose. Drugs are otherwise rarely necessary, while dieting, on the other hand, is of the utmost importance. The diet should be such as to protect the injured mucosa and give rest to the functional action of the stomach. For this reason it is well to give the stomach complete rest at first for some hours, after which time the thirst may be relieved by chopped ice, or by swabbing out the mouth with water or a suitable mouth wash. Small quantities of effervescent waters or cold, weak, unsweetened tea may be sipped. It is especially important that any fluids given at this time should be administered in small amounts.

When food is finally given, it should be given in fluid form. Milk diluted with lime water or soda water, and broths, with perhaps the yolk of an egg, may then be tried, and, after this, more solid diet may be gradually administered.

If purgation is desired, calomel may be used in small doses and combined with bicarbonate of soda. This is particularly useful if an enteritis is also present.

For the anorexia which accompanies and follows this disease a few drops of hydrochloric acid, as recommended by Riegel and Ewald, may be administered—eight to ten drops of the dilute HCl are placed in a wine-glass of water and taken in sips before each meal. Narcotics are rarely necessary, but if required they may be given in the form of suppositories.

SEVERE TOXIC GASTRITIS.

This is merely a more aggravated form of the simple gastritis. It must be remembered that all toxic gastritides, however, are not necessarily severe, though, as many hold, nearly all gastritides are usually toxic. The severe and toxic gastritis, however, is usually caused by the voluntary or involuntary ingestion of concentrated mineral acids—carbolic acid, caustic alkalies, the poisonous metals, such as arsenic, phosphorus, mercuric chloride, calcium chloride, potassium cyanide, etc., and also the essential oils.

SYMPTOMS.—The symptoms vary according to the quantity of poison taken and according to the position of the patient at the time—that is, whether standing up or lying down; in other words, these symptoms vary according to the portion of the alimentary tract against which the irritant comes in contact

The most striking symptoms are pain and vomiting. The pain is usually complained of all the way down from the pharynx to the stomach, and especially along the line of the sternum; it is severe and burning in character.

Vomiting usually occurs soon, especially if something has been present in the stomach at the time It is often repeated, and, as characteristic of the disease, it brings no abatement of the symptoms. Mixed up with more or less foodstuff, there are usually blood, mucus, and perhaps portions of mucous membrane.

The facies is usually anxious and pale, and there is profuse sweating; the pulse is small, rapid, and compressible; the extremities are cold, perhaps cyanosed, and the respirations are shallow, rapid and thoracic (because pain impairs the movements of the diaphragm).

Examination of the abdomen shows nothing characteristic apart from great tenderness, and, if the condition has been extreme, there may be signs of perforation and peritonitis; but this latter occurs only in the severer forms of the disease.

There are all degrees of this form of gastritis; it may be mild with only a few hours of pain, or there may be signs of general intoxication with hæmaturia, icterus, etc. The results are, mainly; stenosis of the œsophagus from subsequent cicatrization; atrophy of the mucous membrane, chronic gastritis, etc.

MORBID ANATOMY.—This varies according to the nature of the case and the extent of the damage; there are always hyperæmia, hemorrhages, and swelling of the mucous membrane, with fatty degeneration of the glandular epithelium, more especially in phosphorus poisoning. Where the erosion has been great there is sloughing, and there may be perforation, or, later, severe hemorrhages, with scars and contractions (stenosis, hour-glass contraction, etc.). The secretory changes are usually great; there is marked diminution of the hydrochloric acid, and there may be gastrectasis.

DIAGNOSIS.—This is based on the sudden severe gastric signs in an otherwise healthy individual, while the poison, or its effects, are usually found on the lips or in the mouth.

TREATMENT.—This consists of lavage, when it is not otherwise contraindicated, and the use of an antidote. If a somewhat longer protection of the gastric mucosa is indicated, rectal feeding may be employed. Special treatment may be required to deal with the sequelæ of the disease.

PHLEGMONOUS GASTRITIS.

Interstitial Purulent Inflammation.—This is a very rare disease, and commences primarily in the submucosa, going through the thickness of the various parts of the stomach. It seems to be sometimes primary, the exact cause, however, being hard to find. More often it is secondary, *i.e.*, metastatic from some other primary focus. It may be diffuse until the whole wall of the stomach is involved to a greater or less degree; or it may be circumscribed, an abscess being thus formed.

MORBID ANATOMY.—The submucosa, especially at the pylorus, is thickened and infiltrated with pus or seropus, and this usually extends more or less to the muscle. The mucous membrane is almost always involved, though often very slightly, and one sees signs of infiltration between the glandular loops. The mucosa is thickened, hyperæmic, ecchymotic; the epithelium is granular or shows fatty degeneration, and there is a small-celled infiltration between the glands. In some cases there are perforations going through the whole stomach (the appearance of a sieve), or ulcers of varying extent may be found.

There are often adhesions with the neighboring organs, and, according to the extent of the pathological changes, the results vary widely. Purulent peritonitis is a not infrequent termination, though infiltration may extend into the duodenal wall or up into the œsophagus, and thrombi may form in the surrounding veins where one or other of the different varieties of pus organisms may be found.

ETIOLOGY.—As a primary affection, we are totally ignorant of the direct cause beyond the fact that it must be a micro-organism. On the other hand, phlegmonous gastritis is secondary to cancer and ulcer of the stomach, to the various general infections, such as pyæmia, variola, scarlatina, etc.

SYMPTOMS.—The symptoms are nearly always acute. The onset is sudden, and there may be a chill, but in no sense are the early symptoms characteristic. It is true that there are severe gastric symptoms, the fever is high, perhaps 105° F., and there are general malaise and severe prostration. Vomiting is nearly always present and persistent, and the vomitus contains mainly mucus or bile.

One never, or hardly ever, gets pus in the vomitus until the abscess has opened into the stomach shortly before death. The case thus often resembles acute poisoning. The pains are very severe, extending over the whole gastric area; there are meteorism and signs of a general or local peritonitis. The fever is usually persistent, septic in type, and there are sometimes repeated rigors.

The pulse, as one might expect, is increased in rapidity, small, and may be irregular. The course of the disease throughout indicates severe general disturbance; the vomiting gradually diminishes toward death. With the development of the disorder there may be coma or delirium, and, following upon this, collapse and death with or without signs of general peritonitis.

The duration is rarely ever longer than two weeks, being usually fatal within the first week. Where the disease is localized an abscess forms and the condition may last somewhat longer, but in other respects there is no difference between the symptoms of the diffuse and those of the circumscribed variety.

DIAGNOSIS.—The diagnosis is never certain, and one usually labors over the differentiation between a general peritonitis and a toxic gastritis.

PROGNOSIS.—Ninety-five per cent. of those cases which are recorded have been fatal. That cases have recovered has only been proven by anatomical preparations, indicating the previous existence of a phlegmonous gastritis.

CHRONIC GASTRITIS.

This consists of a prolonged alteration of the mucous membrane of the stomach resulting in changes in the gastric digestion. The alteration is mainly in the secretions, there being an abundance of mucus and sometimes a stagnation of food.

ETIOLOGY.—The condition may be primary or secondary.

Primary chronic gastritis sometimes follows the acute, though this is uncommon. On the other hand, all the cases of acute gastritis, if persisting for a long period, may assume a chronic form. Thus, for example, dietetic errors, with reference to the manner of eating and chewing of food; the irregularity of meals; overloading of the stomach, especially with indigestible food; the presence of faulty teeth, acting as an impediment to proper digestion—all these separately or combined may induce in time chronic gastritis. Alcohol, especially if undiluted, particularly brandy, is another important cause. Other toxic causes are tobacco, especially if chewed to excess, tea and coffee, spices, certain drugs, drastic purgatives taken too frequently and in too large doses—all of these act as etiological factors, and they are all more potent when combined with a sedentary life.

Secondary chronic gastritis is associated with various diseases of the stomach and the general system; thus, with carcinoma ventriculi, with gastrectasis and adenoma of the stomach, more rarely with ulcer. Diseases of the heart and of the liver, in which passive congestion of the vessels in the stomach are a frequent accompaniment, act as important factors in inducing a chronic catarrhal inflammation of the mucosa.

To a less extent are renal and pulmonary diseases (especially tuberculosis) responsible; still, in certain constitutional diseases, more especially in anæmia, chlorosis, leukæmia, diabetes, and gout, the malady is not uncommon.

MORBID ANATOMY.—The mucous membrane is swollen, thickened, and covered with a layer of tenacious mucus; its color is either dark red or grayish-red, especially around the pylorus.

Microscopical examination of the mucus overlying the mucosa shows that it contains epithelium, which is mostly broken down, and perhaps blood corpuscles; the mucous membrane itself may present isolated hemorrhages, loss of epithelium and erosion; according to the degree of inflammation, one sees degeneration or fibrosis.

The superficial epithelium undergoes more or less mucoid degeneration; the glands are enlarged, partly cystic from retention, and degenerated, while the interglandular tissue shows small-celled infiltration. The capillaries and lymphatics are dilated; the submucosa shows thickening here and there, and sometimes the productive fibrosis results in the formation of warty and polypoid excrescences—what is known to the French as *état mamelonné*.

Pyloric stenosis sometimes occurs as a result, and especially if there is much hypertrophy of the muscular coat.

Cirrhosis of the stomach is a special form of this chronic gastritis, and if advanced it may lead to degeneration and atrophy of the muscular coat.

The final stage in chronic gastritis is an atrophy of the mucous membrane, and this may result in the practical failure of all gastric secretion.

The size of the stomach varies. When there has been serious disease, the organ as a whole may appear shrunken. On the other hand, when the muscular coat has been the one chiefly involved, dilatation of the stomach may be observed.

SYMPTOMS.—The disease may remain for some time latent, or the symptoms may at first be insignificant and then gradually become more pronounced. This stage may continue indefinitely, or, again, the mild symptoms may alternate with periods of complete health. It is well recognized, at all events, that changes in the symptoms from time to time are quite frequent.

Early Signs.—As a rule, chronic gastritis develops slowly; slight dietetic errors cause some discomfort in the epigastrium, with the signs of fulness, pressure, and, perhaps, even pain, either when food is present or when the stomach is empty. There is usually anorexia, together with a bad or a sour taste in the mouth. Flatulence is common and often very troublesome, though the explosion of wind (which is odorless, as a rule) tends to relieve the oppression in the epigastrium and lower part of the thorax. There are nausea, and later on, as a rule, vomiting, which occurs either at the height of digestion or sometimes early in the morning (the result of a pharyngitis, mucus from the throat being swallowed during sleep). Thirst is usually added, and there is a general indisposition for any exertion. The nervous system suffers, too, and neurasthenia is apt to develop; dizziness is not uncommon, more particularly during the digestive period.

Well-Developed Cases.—In these the appetite varies; there is usually, however, anorexia, with satiety after only a little has been eaten. Voraciousness is uncommon, though a special desire for acid, sharp and spicy foods is well known, and often increases with the development of the malady. A disgust for meats is frequent in the well-developed cases. Thirst likewise varies; sometimes it is increased, though not nearly so much as in the case of acute gastritis. There is sometimes a bad taste in the mouth, though this varies; it is usually due to stomatitis or to a chronic pharyngitis. The breath may be foul from the same cause. Salivation or dryness in the mouth may be present. The tongue is furred or red and often sore at the edges.

The dyspeptic signs vary largely according to the secretory or motor disturbance which is present. The quantity and quality of food are of great importance to the patient. Fluids are well borne, as a rule, but solids seem to increase the symptoms. The usual dyspeptic signs—*e.g.*, fulness, oppression, flatulence, eructations, etc.—are common. Water brash is not uncommon; so, too, is cardialgia. Not infrequently there is true pain in the stomach, which, however, disappears rapidly under suitable treatment. Nausea occurs either early in the morning or at the height of digestion, though this symptom is not by any means so common as in carcinoma.

Vomiting is frequently present, though much less common than in acute gastritis. It may be slight or severe, and often occurs in the early morning (vomitus matutinis potatorum), at which time it consists of saliva that has been swallowed and of mucus coming from an old pharyngitis. Such vomitus is apt to be alkaline in reaction. If the vomiting occurs after meals, it takes place usually about an hour and a half after food has been ingested. It is made up of undigested food remnants and thick, ropy mucus, bile, and the various products of fermentation, yeasts, etc. Sometimes the mucus is extremely elastic and tenacious, due, it is thought, to the mucous fermentation of carbohydrates.

General Symptoms.—Constipation is the rule; it sometimes alternates with diarrhea. The nervous symptoms consist of dizziness, anxiety, hypochondriasis, lack of energy. There is inanition, especially among those who are poor and uncleanly, and whose mouths are never properly cared for. Where the intestines are unable to take on the functions of the stomach, malnutrition is very common. The urine varies; urates are often present in large amount.

Although palpitation is not uncommon, the heart, as a rule, presents nothing abnormal.

Physical Examination.—Inspection reveals nothing unless there be stenosis of the pylorus or idiopathic dilatation of the stomach, when inflation or insufflation will demonstrate the increased size and altered position of the organ. The lower border may reach much below the umbilicus.

Palpation shows some tenderness, as a rule, and there may be a succussion splash if atony be present.

The test meal reveals the presence of undigested coarse food with much mucus.

The motor power is either normal or diminished, according as to whether the muscle is in a healthy condition or atonic. When atony exists, the quantity of the test breakfast will be abnormally great and usually contains much mucus.

The results of a chemical examination vary according to the state of the secretory functions. As a rule free hydrochloric acid is diminished or absent. In some cases, on the other hand, there is hyperacidity, pepsin is less in quantity, and the labzymogen is either diminished or absent. Unless atony be present there are usually no organic acids to be found, though sometimes one may find butyric, acetic, and the volatile fatty acids; likewise, though uncommonly, lactic acid.

COURSE.—It is usually of long duration. There are remissions and exacerbations, especially with errors in diet. If taken within a reasonable time and properly cared for, chronic gastritis may be quite readily cured. Recurrences are frequent, however, and alcoholics (in whom the disease is especially common) are very liable to have relapses through repeated indiscretions.

The secretory power is injured, but this may be repaired much more readily indeed than can the motor power when once severely affected. Weakening of the muscular coat results in gastrectasis, which, if of long duration, causes general malnutrition and aggravates the gastritis.

Atrophy of the mucous membrane is extremely uncommon, and the condition known as achylia gastrica cannot be said to be of frequent occurrence.

DIAGNOSIS.—This cannot be made from the symptoms alone, though the long course of the malady, with the above-described signs and symptoms, may aid greatly in the diagnosis. It is essential to examine the stomach contents chemically after a test meal if one would desire any accuracy in his methods of diagnosis.

The *differential diagnosis* concerns, first of all, the distinction between the primary and the secondary forms of gastritis, which latter accompanies hepatic, cardiac, and other diseases. There may be some difficulty in excluding a pure neurosis, in which, however, the effect on nutrition is not so serious, and in which there is usually less mucus in the stomach contents. The symptoms, too, are more variable; there is more neurasthenia; and the symptoms are not always digestive in point of time, nor is it always solid foods alone which cause distress. There may be, on the other hand, a nervous subacidity, and the motor power of the stomach may be somewhat impaired by a long standing neurosis.

The age of the patient is of some importance, inasmuch as a gastritis is not common before thirty, and a neurosis may occur at any age.

In making the distinction from carcinoma it is often quite difficult to determine in the early stages the true nature of the disease. Frequent examination of the stomach contents is necessary; hydrochloric acid is usually absent, and the peptic power is usually diminished early in carcinoma and late in chronic gastritis. Carcinoma is a disease of comparatively short duration, and one must further take into consideration all the various signs and symptoms.

Atrophy of the gastric follicles is determined only by the complete absence of gastric secretions, and is an occasional sequel to chronic gastritis.

Amyloid disease of the gastric mucosa may simulate chronic gastritis, but the differentiation is easily made if amyloid disease be found in other organs and if a suitable cause therefor be present.

There should be no difficulty in distinguishing gastric ulcer from chronic gastritis, inasmuch as the clinical pictures are entirely different.

Prognosis.—The mild cases of chronic gastritis are easily cured. In the more serious cases, on the other hand, especially where the secretion is much diminished and there is atony, the condition is less favorable. When pyloric stenosis is present or atrophy of the mucous membrane or great dilatation of the stomach, the condition may be looked upon as very serious as regards the cure, though the menace to life is not necessarily great. The prognosis should be based less upon the general condition than upon the outlook for securing a sufficient supply of nourishing food, upon the condition of the secretions and the enzymes, and upon the motor power, and, lastly, upon the condition of the intestines, which, if in a healthy state, may largely replace the functions of the stomach. It is well to warn one's patients that relapses are quite frequent, and that exacerbations and remissions are the rule rather than the exception.

Treatment.—A detailed diagnosis is essential to the proper carrying out of the treatment of a case of chronic gastritis. Secondary gastritis must be treated according to the cause, which will involve the therapeutics of the lungs, heart, liver, or general constitution. In the primary cases, on the other hand, the treatment concerns prophylaxis, palliative and curative measures. The curative measures are mechanical, dietetic, and medicinal, and for this reason it is necessary to have a detailed diagnosis of the condition.

One must consider the cause of the disease as well as the condition of the secretory and motor functions and the quantity of mucus present. Prophylaxis is of some importance, and one should, therefore, remove any external conditions which tend to bring on or aggravate the malady. Excesses of all kinds must be guarded against; bad habits cured; the patient should be taught to eat slowly, to chew his food well, and carefully to select his diet both as regards quantity and quality.

The actual treatment is chiefly mechanical and dietetic, and drugs play a comparatively unimportant part. The mechanical treatment consists mainly in the use of lavage. It is necessary that the stomach should be clean before any food enters, and for this reason one must remove any mucus which covers up the superficial epithelium and prevents proper action of the digestive juices. Lavage may be carried out in the early morning or, in bad cases, six hours after dinner (which is usually taken at midday), and the evening meal should be as light as possible. Under ordinary conditions one may wash the stomach out with simple lukewarm water. If, on the other hand, much mucus is present, sodium chloride may be added, or, if there be much fermentation, boracic acid. According to the severity of the case, lavage should be done daily, or every second day, for a few weeks, and on each occasion it should be continued till the water returns from the stomach quite clear.

When atony or much fermentation is present this may require some patience.

When, for one reason or another, lavage is impossible one may employ "natural lavage" by means of frequent administration of mineral waters of various kinds, especially the saline waters, with carbonic acid; those, for example, from Saratoga, containing sodium chloride (Hathorne, Congress Springs), are often beneficial in relieving the stomach of its mucus and inducing a combination of the organic acids. And, again, the alkaline sulphates, such as are combined in Carlsbad waters, are useful for this purpose as well as for relieving the constipation. According to the condition of the secretions and the motor power, the use of these waters should vary. They should be taken cold, where motor insufficiency exists with diminished secretion and constipation. Where, on the other hand, there is irritation in the stomach with diarrhœa, they are best taken hot. Whenever atony exists it is well to remember that only small quantities should be taken at a time. In addition, daily cold baths or shower baths with subsequent friction of the skin are of great benefit. Where pain or great discomfort is present, a wet compress may be placed upon the epigastric area and covered with oil silk.

Electricity is of very doubtful value, though the proper regulation of rest and exercise, which latter should always be moderate, is of the greatest importance.

Dietetic treatment is of prime importance, though often hard to regulate because of individual preferences. The diet must be administered with some regard to the severity of the case; but in all instances the food must be easily digested, and for this reason must require but little on the part of the gastric juice or muscular action of the organ. It must be, further, non-irritating.

When only the scantiest diet is tolerated, milk, preferably diluted with lime-water, may be given at regular intervals, and this, while the patient is at rest, may suffice, provided he can be induced to take from one to two quarts *per diem*. We may say, however, that in the large majority of instances a mixed diet, selected with reference to the needs of each case, is advisable.

When the motor power of the stomach is demonstrated to be normal, one may administer albumens, starches, and fats. If, on the other hand, it is deficient, it is wiser to exclude the fats. When, again, the secretory power of the stomach is defective, a mixed diet is very easily given so long as the motor power remains unimpaired, for the intestines will perform the secretory functions of the stomach. In all cases, however, albuminous food should be finely divided. Starches should form the bulk of the food in those cases in which the hydrochloric acid is deficient, and those starches should be selected in which there is less residue after digestion is complete.

Fats are imperative when malnutrition exists, and for these cases butter and cream form the most easily digested varieties. It is thus essential where possible to give a mixed diet, non-irritating, finely divided and containing as much nutriment as possible within the smallest compass.

In severe cases one may give, in addition to the milk, gruel, milk soups, light puddings, rice, arrowroot, toast, and then eggs. In some cases light meats, if tender, may be added; but it is not wise to add spices nor any rich sauce. The craving which many patients with a chronic gastritis have for spicy things, under the impression that they will stimulate the functions of secretion, are usually not good indications of the best method of treatment.

Of the lighter meats, etc., calves' brains, sweetbreads, chicken, fish, minced beef, are those most preferable.

Alcohol is best avoided unless in the form of very light wine. The quantity of water taken with the meals should be restricted, unless there be hyperacidity, in which case it is well to dilute one's food moderately. Instead of ordinary water, Radnor, Apollinaris, or other effervescing alkaline waters, may be tried with benefit.

The determination of the proper number of meals per day is based upon the condition of the motor power. If this be good, three meals a day may suffice. Where, on the other hand, there is atony, four or five meals, each small in quantity, are more advisable. Coffee, tea, and cocoa may be given except in those cases in which hyperacidity exists. As the patient improves, such vegetables as spinach, carrots, maize, potatoes (mashed), and macaroni, may be added in small quantities and gradually. In severe cases maizena, semolina, and the like may be added. Bread should be stale and not hot. When constipation is marked, it may be well to give stewed fruits, such as apples, prunes, etc. When, on the other hand, diarrhœa is present, stewed blueberries are often very efficacious.

Medicinal Treatment.—Inasmuch as hydrochloric acid is deficient in the course of most cases of chronic gastritis, one may add with some benefit a few drops after each meal. One-half drachm of dilute hydrochloric acid in a tumblerful of water, to be sipped at intervals for an hour after each meal, may be prescribed. On a scientific basis there is little to be gained from the use of pepsin, though practically one frequently does find that its employment seems to afford considerable aid to digestion. Pancreatin in doses of fifteen grains is perhaps better, and should be administered with soda, though rationally this should not be prescribed unless there is some evidence of atrophy of the gastric follicles. After all, these artificially prepared ferments are of little use when one realizes that the intestines carry on the defective actions of the stomach.

It seems of prime importance, however, to give some stomachic before each meal, and for this purpose one may try either dilute nitromuriatic acid, in doses of ♏ x. to xv., or nux vomica, quassia, gentian, or condurango.

In many cases the greatest relief from the more acute suffering incident to chronic gastritis is a pill consisting of silver nitrate gr. ⅙, Pulv. opii gr. ¼, and extract of hyoscyamus gr. ss.

Where fermentation is an annoyance the diet should be carefully looked into; one may sometimes add thymol, or carbolic acid, to the other modes of treatment. For a distinct pyrosis, bismuth subnitrate and sodium bicarbonate, of each ten grains, combined with three to five grains of calcined magnesia, will usually afford relief.

For persistent vomiting lavage is the most rapid means of giving relief. When this is impracticable, a careful adjustment of the diet, with perhaps the administration of one or other of the usual drugs for that purpose, may give benefit.

Constipation is one of the greatest annoyances in these cases. It is well that the patient should develop great regularity in his habits, going daily to stool at regular hours, whether or not there be need therefor. As soon as possible there should be added to his food vegetables containing much cellulose, also stewed fruits, especially a combination of figs and prunes; or in the early morning he should drink cold water or eat a fresh orange; and only in aggravated cases should we resort to either purgation or enemata.

Where purgation is necessary, it is a difficult matter to determine what drugs should be employed; only the mildest forms of purgatives should be given, and of these rhubarb, aloes, and cascara are probably the most beneficial. The use of Carlsbad salts in the morning, as already indicated, is another efficacious means of treatment in aggravated constipation.

VIII. GASTRIC ULCER.

(Synonyms: Round Ulcer of the Stomach, Peptic Ulcer, Simple Ulcer, Perforating Ulcer, etc.)

Definition.—It is a destruction of the mucosa and sometimes of the deeper layers of the stomach wall, of the nature of a degeneration or necrosis; it leaves an open loss of substance, usually round or oval in shape, with clear-cut edges. Such ulcers may be acute or chronic, with or without tendency to cicatrization and healing. In both forms there may be hemorrhage and perforation.

Statistical.—In Berthold's Berlin series ulcer was present in twenty-seven per cent. of all autopsies; in other series the percentage is much less. Thus, in Thüringen it is reported as being ten per cent., and in F. P. Cantlie's statistics from the Royal Victoria Hospital, of Montreal, gastric ulcers formed 0.001 per cent. of all cases admitted.

Etiology.—*Age.*—It is most common between twenty and thirty years of age, though it may occur in childhood, even in infancy, and is seen not infrequently in old age. Kundrat found small superficial ulcers, of recent formation, quite frequently in children, but these are doubtless of a different nature from the true round ulcer. The average age at the Royal Victoria Hospital was twenty-seven and one-half years.

Sex. It is commoner in females.

Occupation has a doubtful relation to ulcer. According to some authorities cooks are predisposed, as are also those who work in glass and porcelain factories, metal turners, tailors, and shoemakers. In Payne's statistics only three out of fifty females are cooks.

It is doubtful whether *trauma* bears any relation to gastric ulcer. *Chlorosis* and *anæmia* are predisposing factors, and *vice versa*, chronic ulcer often leads to anæmia. Again, gastric ulcer is often falsely diagnosed as mere chlorosis, especially as hyperacidity is common in chlorotic girls.

Dietetic Errors.—Alcohol is not a cause of true gastric ulcer. Vegetables and indigestible foods are considered by some as frequent antecedents.

Poisons are not a cause.

Infections.—Tuberculosis, syphilis, trichinosis, and infections generally are a frequent cause of gastric ulcer, but not of those having the characters of the ordinary round ulcer. That an ulcer occurs in other affections does not imply that the gastric round ulcer has the same etiology, nor can we infer, from the mere facts that ulcers are found lying opposite to one another, and that they manifest an œdematous condition of their immediate surroundings at the time when perforation occurs, that they owe their origin to an infection. These ulcers are purely necrotic in all their typical pathological characters.

Pathogenesis.—It would seem that the two main factors are: (*a*) Some interruption to the circulation going to the stomach, or anæmia. (*b*) Hyperacidity. It is probably the increased hydrochloric acid which keeps the ulcer chronic. In anæmic conditions the vessel walls are liable to changes, especially fatty and atheromatous. Normally, the gastric juice does not digest the mucous membrane, because the blood furnishes the neutralizing element. When ulcer occurs, we conclude that:

1. There is increased hydrochloric acid, and it is not sufficiently neutralized by the blood.

2. The circulation is in one way or another restricted, so that neutralization is impossible.

3. The blood shows diminished alkalinity.

The second of these is doubtless of greatest significance, though proof of the real pathogenesis is absolutely lacking.

Morbid Anatomy.—*Situation.*—These ulcers exist wherever gastric juice flows. The posterior surface is the commonest site, ulcers being found there in 42 per cent. of all cases, especially near the pylorus. In 15.6 per cent. the pylorus is the site, while in 26 per cent. of all cases the ulcer exists either in the lesser curvature or in the pylorus. They are on the anterior wall in 4.9 per cent., on the greater curvature in 2.4 per cent., and at the cardiac end in 0.2 per cent.

Number.—These ulcers are usually single, but sometimes they are multiple. In one of Berthold's cases there were thirty-four. When multiple, they may all seem to be of the same duration, or some may be in a state of healing, while others seem to be quite recent.

Shape.—The more acute ulcers are punched-out in appearance, round or oval, and sharp in outline, while the chronic ones are shelved or terraced, the widest diameter and greatest loss of substance being at the mucosa, the ulcers becoming gradually narrower as one approaches the serosa (funnel-like). This would seem to correspond to the distribution of the blood-vessels. Orth has drawn attention to the fact that these ulcers are often oblique, *i.e.*, their long axis corresponds to the direction taken by the blood vessels. Often these older ulcers are irregular in outline, spread out, and, with the mucosa, rolled inward and thickened at the edges. Cicatrization may often be seen progressing at various portions of the walls. The muscles beneath are shrunken. The floor is smooth and grayish-brown or red, rarely ragged.

Size.—The usual size varies from 2 cm. in diameter to 3–4 cm. In some instances, however, they may be as small as 1 cm., or as large as 10 cm., in diameter, and sometimes the ulcers form a ring more or less completely surrounding the organ.

Healing and cicatrization are common. Scars vary in size, and—according to their size and situation, and to the amount of contraction which followed the healing process—they may or may not cause perceptible deformities in the organ and corresponding functional disturbances. The deformities thus caused comprise hourglass contraction, pyloric stenosis and gastrectasis, and cardiac stenosis. The process of healing begins with proliferation of the adjoining fibrous and glandular tissues, and finally, when healing is complete, the central portion is occupied by fibrous or adenoid new growth consisting of cylindrical cells arranged about a lumen, no opening existing toward the stomach cavity and no secretion flowing from the cells. Fibrous tissue replaces lost muscle cells. Sometimes healing leaves, in the vicinity of the ulcer, chronic inflammatory areas which tend to erosions and recurrent bleeding. This may be serious, and even fatal, if large vessels are involved.

SYMPTOMS.—There may be no characteristic symptoms, the first discovery of a gastric ulcer being made unexpectedly at the autopsy. Then, again, the first evidence may be a sudden or perhaps fatal hemorrhage; or the peritonitis following a perforation may give the first indication to patient or physician that an ulcer has been present. The symptoms may simulate spinal disease, hysteria, hyperacidity, and only upon the appearance of more serious signs does the diagnosis become clear.

Dyspeptic Signs.—When the symptoms are marked there is a sense of weight and pressure coming on in one-half to two hours after meals—after a time becoming more aggravated. These may be the only signs throughout the whole disease, or others may and usually do follow. Pain develops, and then follows vomiting during the digestive period; the pains are in the area of the stomach, often of a piercing nature and felt in the back, and a small localized area of tenderness can be detected. There are often signs of hyperacidity, such as acid eructations and heartburn. The tongue, though often coated, is usually clean, red, and moist. The appetite varies, and, though it is usually good, patients fear to eat because of the chance of inducing pain. Thirst may be present. One or more hemorrhages may occur, and pallor usually becomes marked, with perhaps weakness or collapse. The stools may contain blood, and there is usually constipation, due to the anaemia, the nature of the food, the lack of exercise, and the vomiting. Remissions and exacerbations occur, and the disease may run on for a very long period.

The general condition remains good, as a rule, though the anaemia and emaciation are sometimes marked. Nervousness, melancholia, headache, and dizziness are common; so, too, is amenorrhœa or dysmenorrhœa. Fever is usually absent unless complications arise—especially peritonitis, and sometimes hemorrhage. The urine is lessened in quantity when vomiting occurs or when less nourishment is taken. It is usually less acid, especially when there is gastric hyperacidity.

Special Symptoms.—*Pain* is described as boring, burning, gnawing, rarely lancinating or cramp-like, and radiates often to the back. It is paroxysmal, and may be at times excruciating. It occurs during digestion, either at once after taking food or at the height of digestion. The hyperacidity increases it. When the ulcer is at the pylorus, the pain may not appear for from three to four hours after meals, and will thus lead one to suspect a duodenal ulcer. It is distinctly aggravated by a large amount of food or by food that is solid. On the other hand, the pain is relieved by rectal alimentation. It is frequently localized, and nearly always referred to the same spot, while pressure of the hand or clothing usually aggravates it. It may or may not be altered by a change of posture. The most tender spot is usually in the epigastrium below the xiphoid cartilage, or it may be located to the left of the spine between the seventh and twelfth dorsal vertebræ. It is an important diagnostic feature that the tenderness of the stomach corresponds to the seat of pain after eating, and that the situation of this tenderness rarely varies during the whole course of the malady. The cause of the pain varies, it being due sometimes to the food, sometimes to the gastric movements or to involvement of the peritoneum. Scars do not usually cause pain unless there are adhesions.

Vomiting is less constant than the pain. Cantlie found it in seventy-nine out of eighty-five of his cases in Montreal. There may be merely nausea and flatulence, and never any vomiting, or the vomiting may appear only at intervals of a week or more. The vomiting occurs sometimes immediately after taking food, but usually one, two, or three hours later—during digestion, and generally at its height. The pain is relieved by it. To a great extent the onset of vomiting depends on the quality of the food; it occurs less often after taking fluids than after taking solids, and especially coarse heavy foods.

The *vomitus* varies according to the food and its sojourn in the stomach. Digestion is usually quick, and albumens are well divided on account of increased hydrochloric acid. At other times the food is quite undigested, and the vomitus is acid and "puts the teeth on edge."

Hæmatemesis occurs in more than twenty-five per cent. of all cases of gastric ulcer. In the statistics of University College Hospital the percentage was eighty-four; at the Royal Victoria Hospital sixty per cent. had hæmatemesis. It is well to remember the other causes, especially erosion of the mucosa elsewhere than in the stomach, with oozing of blood which may be fatal and which may show no signs at autopsy of its origin. There is also the possibility that the hemorrhage may be dependent upon some circulatory disturbance, especially mitral stenosis, or upon cirrhosis of the liver, splenic anæmia, leukæmia, uræmia, tabes dorsalis, fraud, etc.; and one must include in the diagnosis of hæmatemesis the previous taking of wine, iron, coffee, fruit juices, etc., which may simulate altered blood. The history, too, must be carefully taken to insure the gastric origin, and the mouth, throat, and lungs must be thoroughly examined, as well as the liver, spleen, and blood.

In hemorrhage from the stomach the source is usually arterial, the vessel becoming eroded during the development of the ulcer. Hæmatemesis occurs in about one-third of all ulcer cases. The blood is usually dark in color, the hæmoglobin being changed to hæmatin by the hydrochloric acid. Few corpuscles are then left unaltered, and the vomitus may resemble coffee-grounds, though it may have a brighter color if a large vessel be eroded and if the blood be vomited quickly after it escapes from the vessel. The matter vomited, which may be copious in quantity, contains coagula and bits of food, and is acid in reaction but not foamy.

The hemorrhage may be fatal at once, without any blood being ejected from the stomach—as, for example, when a comparatively large artery is eroded. This, however, rarely happens; usually, when there is a serious hemorrhage, the patient vomits a large amount of bloody fluid, becomes pale, cold, semi-conscious, and complains of dizziness and headache. The pulse is rapid and small, and there is a warm feeling in the epigastrium. Sometimes the hemorrhages are oft-repeated in spite of care, and sometimes again one or more insignificant ones take place, and then they cease altogether. Some of the blood gets into the intestine, and during the next day or two the fæces are black, or brownish-black, with a shining surface. This color is due to the intimate mixing of blood and chyme in the small intestines.

Sometimes all the blood escapes per rectum, and there is no hæmatemesis. This occurs where bleeding is more gradual, and there is thus less tendency to vomiting.

Tests for the presence of blood, especially in the fæces: Teichmann's test with hæmin crystal formation is sometimes unsatisfactory, and one may not obtain the crystals. The spectroscope is better. Weber's test is the most reliable. It is made as follows: Rub up a little of the fæces with water, to which has been added one-third volume of glacial acetic acid; shake out with ether, and, on its clearing up, take a few centimetres of the ethereal extract and treat it with ten drops of tincture of guaiacum and from twenty to thirty drops of turpentine; a blue-violet color results if blood is present.

Objective Signs.—But little is gained from an examination of the stomach. A localized tender spot, often no larger than 2 to 3 cm. in diameter, may be present, and is felt often "through to the back" on deeper pressure. It is found most often just below the xiphoid cartilage. Very frequently, however, the tenderness is not so localized, and a more diffuse soreness is felt in the epigastrium on palpation. No tumor is palpable in fresh ulcers. In *older ulcers*, where scarring has occurred at the pylorus, the signs of stenosis may be present; peristaltic movements, and even a tumor, may be seen on inspection, while palpation may reveal the latter as a more or less movable mass situated at some part of the upper right quadrant of the abdomen.

Diagnosis.—In making a diagnosis of ulcer of the stomach one should first exclude the possibility or likelihood of gall-stones, simple gastralgia, simple hyperacidity, cancer, renal calculus, aneurism of the aorta, and spinal disease. The points which favor this diagnosis are: sex (female), pain after taking food, tenderness over the region of the stomach, hyperacidity, vomiting, usually preceded by pain, and hæmatemesis.

A diagnosis of the seat of the ulcer is usually impossible. The ordinary evidences mentioned by many writers are now known to be quite unreliable. Then again, there may be several ulcers present at the same time, and we may overlook this in laying stress on the site of one which gives evidences of being located at a certain spot.

The Use of the Stomach Tube for Diagnosis of Ulcer.—The contraindications are: Recent hemorrhage, or where an ulcer at the cardiac orifice is suspected, or where there is but little doubt in regard to the existence of a gastric ulcer.

Riegel asserts that when the introduction of the tube is "carefully done" there is but little danger. At all events severe efforts at vomiting are dangerous, and expression is an unwise method; but if the tube is readily taken it may be safe to resort to this procedure.

Prognosis.—Recovery takes place in most cases in which perforation has not occurred. Fatal hemorrhage occurs in less than five per cent. of all cases. One sees post mortem twice as many scars as fresh ulcers. In men the mortality is twenty-two per cent., in women six per cent.; in both together eight and one-half per cent. for all cases. Older ulcers are more favorable. Relapses are frequent, and may occur after several years. Sometimes a new ulcer forms alongside of an old and chronic one. Cancer may form on top of an ulcer.

Complications.—Perforative peritonitis; perigastritis, suppurative and adhesive; subphrenic abscess; fistula between stomach and adjacent organs; abscess of liver and chronic hepatitis; acute and chronic pancreatitis; pressure on or constriction of main bile ducts, with jaundice; contraction of scar followed by the development of a cancer; hour-glass stomach; pyloric stenosis; dilatation of stomach; cardiac stenosis.

Perforation is one of the most serious complications in gastric ulcers, and occurs in about fifteen per cent. of all cases. It takes place from the deeper extension of the ulcer, and is most common on the anterior wall, where there is greater mobility of the part and less tendency to the formation of adhesions. It may, however, and often does, occur in the posterior wall.

Partial or general peritonitis may follow. Partial peritonitis is usually confined to the epigastrium and left hypochondrium and is usually purulent, or pus may collect in the lesser omentum if the perforation is located posteriorly. General peritonitis occurs chiefly when the perforation takes place rapidly and before any previous adhesions have formed.

The perforation may extend directly or indirectly (*i.e.*, after adhesions have formed) into adjoining organs or tissues; no serious results may follow, or the affected organ may show more or less serious symptoms and signs. Perforation into the pancreas or liver may cause abscesses or chronic inflammation in either organ. Subdiaphragmatic abscess sometimes develops. If the perforation extend into the gall bladder, gall-stones may fall into the stomach through the fistulous opening. The intestines may be penetrated and severe diarrhœa occur, with bloody or purulent fæces, or fæcal vomiting may take place instead. Rarely, the ulcer perforates the abdominal wall itself, penetrating muscles and skin and leaving an external fistula. The pleural cavity is sometimes invaded, with the formation of a pyopneumothorax; more rarely, the lung is penetrated and the sputum may then contain stomach contents. Rarely, too, the pericardium is penetrated.

The Symptoms and Signs of Perforation.—The onset is usually sudden; indeed, it may be the first and only sign of the ulcer. The patient need not be overcome and incapacitated at once; oftentimes he is able to walk into hospital with such a perforation. It commonly follows some strain (vomiting, exertion, etc.) or trauma, or a hearty meal. Pain is the earliest sign; it is usually referred to the epigastrium, spreading soon to the right and left, but not leaving its original site. There is no pain or difficulty during micturition. Dyspnœa soon follows and deep breathing causes pain about the diaphragm, so that these cases are sometimes mistaken for acute pleurisy.

Collapse and prostration supervene, although in some cases remarkably little prostration is observed—a fact which is apt to mislead, all the more so as the general signs may greatly improve after a few hours, before graver symptoms develop. The face then is anxious, often pinched, and there is apt to be great restlessness. The pulse is usually accelerated, though sometimes it is normal, and the temperature may be but little altered immediately after perforation has occurred; usually there is slight fever. The abdomen may be flat and tense; sometimes it is distended; the muscles are rigid. Tenderness is chiefly in the upper abdominal zone, mostly about the epigastrium. Percussion may or may not give dulness here, and the liver dulness need not be obliterated. On auscultation a friction rub can often be heard over the diaphragm, and sometimes the gurgling of fluid through the perforation.

Though it is commonly taught that vomiting never occurs after a perforation, this cannot be relied upon, as experience teaches the fallacy of too strict an adherence to this rule. Attention should be paid to the base of the thorax on the left side, where one often obtains restricted movement, localized pain and tenderness with dulness in the lower axillary region, and other signs of fluid. Fluid may collect beneath the diaphragm, about the anterior and external surfaces of the spleen, or in the lesser peritoneum. Later on, one may obtain the usual signs of general peritonitis.

Treatment.—Rest in bed is essential for at least four weeks after the diagnosis has been established and the treatment commenced. After this, the transition from bed to walking about must be very gradual, and the patients should be made to rest after every meal. This precaution should be observed for some months. It is true that even this does not always suffice, and a much longer period may be necessary; but apart from active operative interference, rest to the body and to the stomach are the main essentials in the present state of our knowledge.

Dietetic.—In all cases it is well, during the first few (three to eight) days, to depend exclusively upon rectal alimentation. In this way the stomach is given a complete rest. Every six hours the patient should receive (by way of the rectum) six ounces of broth with egg, and if necessary a little whiskey. Each enema should contain a little salt; the bowel should each time be first washed out. Any other diet is apt to cause distention, to increase the hyperacidity, to induce vomiting, and thus directly or indirectly to prevent healing of the ulcer. At most, a little water or chopped ice may be taken.

When food is admitted by the mouth it is best to commence with milk and lime-water, strained oatmeal gruel, or albumin-water—at first in small quantities (a few ounces)—every two hours, and to combine this as required with the nutrient enemata. Then, while gradually increasing the amount of food furnished to the stomach, one may reduce the rectal feeding. At the end of four weeks one may add finely divided albuminous food, minced white flesh, chicken, partridge, pounded fish and tender beef, and light puddings. *The greatest care should be taken in changing to a more solid diet, and it is always safer to go very slowly at this stage.* After six weeks, red meats may be given. One must, however, take special care with the diet for several months after there is an apparent cure, and all coarse, irritating, spicy, and rich foods must be avoided.

Medicinally, Carlsbad salts in small doses (one drachm), given in hot water in the early morning, will often be found beneficial, and bismuth, especially the subgallate, in doses of twenty to thirty grains, three times daily, affords great relief. Again, with other patients, the combination of sodium bicarbonate and calcined magnesia assuages the pain and the burning.

The constipation may not be relieved by the Carlsbad salts; in which case enemata of soapsuds should be administered. Lavage may be used where there is a very intractable stomach, and sodium bicarbonate may be added to the water used.

Pain, if severe, may need morphia; a wet compress over the epigastrium is often soothing.

For *vomiting*, ice, bismuth, and nitrate of silver (gr. $\frac{1}{4}$).

For the *hæmatemesis*, absolute rest and quiet, ice to suck, and small doses of adrenalin chloride in solution of 1 to 1,000, may be effective. For the restlessness one may use morphine hypodermically. For severe recurrent hemorrhage surgical intervention may be necessary and is often most successful.

Surgical Treatment.—If the bleeding be of a very serious character, recourse should be had to operation. The indications for surgical interference in gastric ulcer are briefly:

Repeated, profuse and dangerous hemorrhage.

Scars which have resulted in tumor formations, which greatly interfere with the motor function. In these cases gastro-enterostomy is recommended. The operation is also indicated where active ulceration exists, inasmuch as draining the stomach suffices to heal the ulcer. It can be performed, too, very quickly. In some of the cases, however, pylorectomy is required or advisable, and in others pyloroplasty.

Purulent perigastritis, especially if subphrenic or thoracic.

Perforation into the abdominal cavity. In this condition operation must be done early, otherwise the case is almost certain to end fatally. Early operations are followed by more than fifty per cent. of recoveries, in some institutions the proportion being even greater. Dr. James Bell's cases at the Royal Victoria Hospital, Montreal, numbered ten, with nine recoveries.

In hour-glass contraction one of three operations is employed, viz.:

Gastroplasty, gastro-enterostomy, or gastro-gastrostomy.

[For further details concerning these operations consult the article on *Stomach and Œsophagus (Surgical)*.]

IX. CANCER OF THE STOMACH.

Carcinoma Ventriculi.

This is a malignant epithelial neoplasm of the stomach. About one-half of all cancers arise in the stomach.

Etiology.—It occurs chiefly between the ages of forty and seventy, and most of all between the ages of fifty and sixty. Lebert's statistics show that only 1 per cent. occur under 30 years, 17.6 per cent. between 30 and 40 years, 60.7 per cent. between 40 and 60 years, 16.3 per cent. between 60 and 70, and 4.4 per cent. over 70 years of age.

It is a little more common in males than in females. There are no climatic conditions of importance, except perhaps the fact that it is more rare in tropical countries. Such, at all events, is the evidence given by physicians residing in those lands.

Heredity seems to acquire a more and more doubtful value in the etiology of cancer.

Parasites have not yet been proven as a direct cause, nor has irritation as such been definitely associated with the disease as its chief etiological factor. Chronic ulcer of the stomach, however, is a frequent antecedent.

Morbid Anatomy.—Cancer of the stomach is a typical epithelial overgrowth extending to the other coats of the organ, and thence to neighboring glands and to other organs by continuity and by way of lymph and blood channels. It is nearly always primary in this part of the body, rarely secondary.

The Situation of the Growth.—The pylorus is the most common place of origin, the growth often starting at the tubercle, while next in frequency come the lesser curvature and the cardia; the fundus is nearly always free. The statistics of Hahn on this point show that out of 170 cases 60 were at the pylorus, 27 at the lesser curvature, 40 at the cardia, 7 in the anterior wall, and 7 in the posterior wall; in 8 cases the disease began in the greater curvature, and in 21 the whole organ was diffusely involved.

Orth's statistics differ somewhat from Hahn's. He found that in 60 per cent. of all cases the pylorus was involved chiefly, while in 20 per cent. the lesser curvature was the seat of origin; the cardiac orifice was involved in only 10 per cent. of all his cases, while the remaining 10 per cent. were distributed more or less unevenly over the other portions of the organ.

The Neoplasm.—This is either circumscribed or diffuse in character. When circumscribed it projects as a villous or fungoid growth, with or without central degeneration and ulceration; when diffuse it extends along the submucosa, causing thickening and rigidity of the wall and a roughening of the mucosa, which may be ulcerated in various portions, while the rest of the mucosa shows either a chronic inflammation or hemorrhage.

Orth distinguishes four forms:

1. The cylindrical celled, *i.e.*, the soft fungous-like growth, which often forms papillary projections on the surface. These projections show microscopically an adeno-carcinomatous arrangement. Such growths are oftenest at the pylorus, where they are sharply delimited toward the duodenal end. Necrosis, ulceration, and hemorrhage are apt to occur, and perforation may result.

2. The medullary or soft form, which is mainly ulcerative, and shows a projecting wall. Degenerative processes are common, and the growths may extend to the serosa or through it. Extension to the glands is especially common in this variety, and it is very rapid in growth.

3. The scirrhus form, with carcinoma simplex as its subvariety. This is the hard form of carcinoma ventriculi. Instead of being circumscribed, it shows a more diffuse thickening of the whole wall. The mucous membrane may be superficially ulcerated, but there is a tendency to scar formation on the surface which may be either rough or smooth. Here the cancer extends gradually into the surrounding parts, more especially into the muscles, and the microscopic appearances are such as to render the differential diagnosis from chronic simple ulcer, or from simple cirrhosis of the stomach, either difficult or impossible without a microscopical investigation. These cancers tend to shrink, and, inasmuch as they are most common at the pylorus, stenosis of that orifice is apt to follow; moreover, adhesions are very commonly found between the pylorus and the surrounding parts, which tends further to increase the liability to stenosis.

4. The colloid variety. In this form there is a diffuse thickening of the wall due to the presence of a jelly like, translucent material, brownish-gray in color, the result of colloid degeneration of the cancer cells. Shallow ulceration accompanies this extension and secondary nodules are frequent. Here, too, the pylorus is the commonest seat of origin, and from this point the cancer may spread far and wide. In some cases, however, the stomach is really smaller than normal.

These different forms of cancer of the stomach are apt to be combined in one and the same case, and the name carcinoma simplex is given to that form in which the medullary and the scirrhous varieties are more or less evenly mingled.

The Shape of the Stomach.—This depends upon the situation and upon the variety of the tumor. Where the pylorus is involved there is apt to be dilatation; where the cardia is the original site, the stomach may be smaller than normal; and where the body is involved, there may be either a diminution in size or, if much scarring has taken place, there may be an hour-glass contraction or some other perversion of the original form.

The Position.—There may be ptosis of the stomach, or, if the growth at the pylorus be heavy and free, the stomach may assume a more vertical position, while in other cases there is no alteration whatever from the normal.

Extension.—The advance of the disease may be confined to the stomach, in which organ it causes degeneration and hemorrhages, great or small, and such hemorrhages may be fatal. There may be perforation with general peritonitis, or merely a local peritonitis with adhesions. This, however, is evidently a rare event, for out of forty cases at the Johns Hopkins Hospital only six were found to have such a condition. The perforation may result, however, in establishing an abnormal communication with other organs or cavities of the body, or with the spaces in between the various organs and tissues of the abdominal cavity.

The cancer again may extend to the œsophagus, or by contiguity to any other part in the vicinity. It may extend by way of the lymph channels, getting into the glands, chiefly those about the portal vein and cœliac axis, and eventually it may reach the thoracic duct, whereby it will involve (by retrograde progression) the left supraclavicular gland as well.

The liver is involved in more than twenty-five per cent. of all cases, chiefly by way of the blood or lymph channels; and inasmuch as growth in the liver is easy, from the nature of its tissue and constituent parts, the secondary nodules there may be much more extensive than was the original disease in the stomach.

The peritoneum and omentum may likewise be involved through extension by the lymph channels; so, too, may the pancreas, in which case sugar is usually present in the urine.

Secondary Cancer of the Stomach.—This is a rare condition, and is due to direct contact, the disease extending from the pancreas, liver, œsophagus, etc., or, as in one case recorded, by implantation from a primary cancer of the tongue. Another method by which it may arise is through metastases from the blood. Welch has collected 37 cases in all; of these, 17 were secondary to cancer of the breast, 8 to cancer of the œsophagus, 3 to cancer of the mouth.

In the recent series of the Johns Hopkins Hospital, reported by Osler and McCrae, three cases were found—two associated with primary cancer of the pancreas and one with primary cancer of the uterus.

The morbid anatomy is in all respects similar to that of other cancers. So far as the other organs are concerned, it may be stated that brown atrophy and fatty degeneration are often observed.

SYMPTOMS AND COURSE.—*The Onset.*—This is usually insidious, and shows mainly a persistent dyspepsia, more or less progressive, with pain in the abdomen and loss of flesh. As time goes on, vomiting occurs and cachexia gradually develops, until after some months, or perhaps at the end of two or even three years, the patient succumbs to the disease.

Examination of such patients in the fairly advanced stage shows profound weakness, an earthy hue to the skin, emaciation, and vomiting of more or less undigested food and coffee grounds, which show on chemical examination the presence of abundant organic acids, and especially lactic acid.

Examination of the abdomen shows, in the majority of cases (because the majority are pyloric in origin), a marked dilatation of the stomach with succussion splash, tenderness in the epigastrium, and perhaps a tumor.

The symptoms, of course, vary according to the stage of the disease, the extent and the pathological nature of the growth, its site, and its direction of progression.

The Individual Symptoms.—The onset may be latent entirely, and development may occur under the picture of senile marasmus, or a chronic gastritis, or a primary cancer of the liver; or the condition may be found accidentally at autopsy in death from other causes.

In nearly all cases the onset is insidious. In the majority of cases there has been previously no dyspepsia, and the patient may seem to be suffering from a mild gastritis, though without apparent cause. There are loss of appetite, a sensation of fulness after taking very little food, and flatulence. Sometimes indeed the onset is sudden, after an acute indigestion or influenza. This is less marked in young persons, as has been shown in the cases of Osler and McCrae.

There is, however, one set of cases in which the onset is exceptional—viz., those in which the cancer is engrafted upon a previous ulcer with all its classical signs. Even when there is cancer of the cardiac end the onset is gradual, except perhaps that the pain comes earlier, and is present not only after meals but at any time during the day.

The Appetite. The appetite becomes gradually worse; very little satisfies the patient, and there is rarely a good appetite for any length of time. As a rule there is anorexia; meat is especially abhorred. That anorexia is more marked in young persons cannot be considered as an infallible statement.

Pain. Pain is rarely absent. In Dr. Osler's series thirteen per cent. ran a painless course, but even when present the pain as a rule is not intense; not so severe, at all events, as in ulcer. There are a painful distress and a dull ache in the stomach region rather than true pain, and the symptoms are rarely localized. It cannot be said that any relation exists between the absence of pain and the site or nature of the tumor, nor can it be said that there is any relation between the presence of the tumor and the site of the pain.

Food often increases the pain, especially late in the digestive period, unless the cancer be at the cardiac end. Sometimes the pain has no relation to the ingestion of food, but is continuous. It may radiate, more especially to the back, or, if the cancer be at the cardiac end, it will be referred to the vicinity of the sternum. There is nothing characteristic about it. It is less acute, as has been said, than it is in ulcer of the stomach, and if there be great tenderness a complication may be suspected. With pyloric stenosis especially, there is a sense of gastric unrest; cramp-like pains due to the peristalsis may be present.

Vomiting. This is a very frequent symptom, occurring in from eighty to ninety per cent. of all cases. It usually appears late in the disease, and is especially common in cancer of the pylorus. In such cases there are dilatation of the stomach and stagnation of food. As a result the vomiting is often severe and consists of coarse, undigested acid food with a foul odor or one of fæces (in the latter case even when there is no communication with the bowel).

Much mucus is present when the cancer is at the cardia, and in such cases the vomiting is more of the nature of a regurgitation of œsophageal origin than a true vomiting.

In some cases there is no vomiting at all, more especially when dilatation is absent, or when the cancer is on the greater curvature or on the posterior wall of the stomach. Absence of vomiting does not depend upon the presence or absence of ulceration. Sometimes, again, vomiting, which has been very severe, may cease more or less suddenly, as, for example, when the pyloric stenosis breaks down and gives a new exit for the food into the duodenum.

As to the time of its appearance, the vomiting usually occurs late in the afternoon or evening; it is sometimes more or less periodical, every two or three days only, in which cases the matter vomited is often copious (several litres), and its appearance depends chiefly upon the nature of the food ingested.

Hæmatemesis. Hæmatemesis occurs in less than half of all cases of gastric cancer. It is associated with small parenchymatous hemorrhages from degeneration of an ulcerated tumor, or, more rarely, with the erosion of a larger vessel, in which case a fatal result may ensue, though this is rare. The amount of blood is usually small; it oozes slowly and remains a long time in the stomach. For this reason it becomes rapidly changed in color and nature, and assumes the appearance of chocolate or of coffee grounds, and the blood cells in it are more or less altered and much pigment is formed.

Bowels. These are at first costive; constipation indeed is much more common than is diarrhœa, though sometimes diarrhœa and constipation alternate. There is no relation between the growth itself and the regularity of the bowels.

Objective Signs.—Nutrition. At first the nutrition is good, and it should be remembered that a good nutrition is not necessarily incompatible with the presence of a cancer of the stomach, unless the disease has been of a year's duration. Again, the patient may, after being emaciated for a certain length of time, regain his weight for a brief period under the employment of lavage, a proper diet, etc. As a rule, emaciation follows soon upon the onset. The skin becomes lax and assumes an earthy color, the muscles waste, and the patient becomes dried up and cachectic. Loss of strength goes hand-in-hand with loss of weight.

Fever. Fever occurs probably in about one-half of the cases; it is usually very slight and manifests itself at varying intervals. The type varies; it may be slight and intermittent, or very irregular, or sometimes—and more especially when ulceration and metastases are present—there may be periods of high fever following sudden rigors. Such a condition is usually associated with absorption of toxins, where fever is persistently high, and one is justified in suspecting an inflammatory complication, such, for example, as peritonitis or pleurisy.

The Tongue.—The tongue is apt to be thickly coated, though this varies very much with the condition of the mouth and teeth, and one may find for months a tongue that is perfectly clean while the cancer is progressing.

Taste is apt to be much altered in various ways, and the patient, if an habitué of tobacco, loses a desire for smoking.

The neck may show evidences of swollen glands, as may also the left axilla. Swollen glands, however, are not common; they are associated with involvement of the thoracic duct, and when present form a valuable sign of gastric carcinoma. And yet their absence is in no wise of value as a proof against cancer.

The Abdomen.—Inspection. This is of great importance in the examination for gastric carcinoma, and Osler has drawn especial attention to this fact. One should examine the abdomen for unevenness in the furrows below the ribs, for fulness in the epigastrium, for nodules in the skin or about the umbilicus, for peristalsis and antiperistalsis; this last especially is of great importance in the diagnosis of pyloric stenosis. One may even see a tumor when present, as well as gastrectasis and gastroptosis. Such an evidence of tumor implies either its large size (because if at the pylorus or cardia it would be covered over by liver or ribs), or else a gastroptosis which exposes the otherwise covered portion of the stomach.

The mobility of the tumor may also at times be ascertained by inspection, both when adhesions are present and when there are no adhesions. Various positions of the body too may alter its situation, while artificial inflation may cause it to become more prominent or to disappear. It is to be remembered that a full stomach sometimes pushes tumors up underneath the liver and makes them thus temporarily disappear. Pyloric tumors are the most movable of all, and they are especially so when they are circumscribed and solid.

Percussion is of but little importance in the examination for gastric cancer. When the tumor is present there may be a dull tympany; when gastrectasis exists percussion reveals the enlarged size of the organ and aids in its proper delineation.

Auscultation and auscultatory percussion have practically no value in the physical examination for gastric cancer. Occasionally, when the cancer is obscure and involves the cardiac end of the stomach, one finds the deglutition sounds delayed or lost.

In the absence of a tumor the diagnosis often remains doubtful, though other signs are valuable positive aids.

The Functional Signs.—It must be remembered that there is no pathognomonic sign of cancer. Each item of evidence must be considered in connection with others, and only from the combination of signs and symptoms is one able to make a positive diagnosis.

The Motor Power.—This is usually greatly diminished; it depends to a large extent on the site of the neoplasm. When the tumor is at the cardiac end of the stomach, the motor power is but little impaired until extension has occurred to other parts of the stomach wall, or until a concurrent catarrh of the mucous membrane is present. When the cancer arises at the pyloric end, however, the motor power is rapidly impaired, and often to an extreme degree. This is more especially the case when there is complete obstruction without a sufficient compensatory hypertrophy of the gastric muscular coats. Hence we have pyloric stenosis with gastrectasis and atony of the wall.

When the cancer involves the body of the stomach, the motor power is impaired in more than one-half of all the cases. It is altered mainly in two ways: firstly, by infiltration of the walls with cancer; and secondly, by simple weakness of the muscular tissue due to a toxæmia and to cachexia.

Motor insufficiency appears early, especially in the case of pyloric cancer, and increases progressively till marked retention of food occurs. Indeed, the retention is often extreme, and foreign bodies remain for weeks and even months in the stomach without finding an outlet.

The Secretory Power.—The secretory power of the stomach is likewise disturbed, and there is diminution of the hydrochloric acid and subsequently of the peptone and rennet ferments.

With regard to the presence or absence of hydrochloric acid in cancer of the stomach, the following facts are important:

1. Hydrochloric-acid secretion usually diminishes with the development of the cancer until free hydrochloric acid is ultimately permanently absent. This occurs in from eighty to ninety per cent. of all cases, very often early in the disease. It should be remembered that one examination alone does not suffice, inasmuch as hydrochloric acid may be only temporarily absent in this as in other diseased conditions of the stomach.

2. Combined hydrochloric acid is also quite often absent.

3. Hydrochloric acid is not always absent; indeed, it may be present up to the end. This is usually coincident with either a very localized tumor, where the rest of the mucous membrane remains more or less intact, or it may occur when the cancer develops upon a previously formed chronic ulcer. In this latter case the hydrochloric acid may be increased. The presence of hydrochloric acid in a test meal is no proof against the presence of cancer in the stomach.

4. The absence of hydrochloric acid in the stomach contents is no proof in itself of the presence of cancer. Such a condition arises in many ways; for example, in neuroses of the stomach, cardiac disease, gastritis, febrile conditions, amyloid disease, atrophy of the gastric glands, etc.

The presence of organic acids is a frequent sign in cancer of the stomach. The chief organic acids found are lactic, butyric, and acetic acids, which arise as a result of fermentation, which occurs so frequently in cancer in association with the presence of hydrochloric acid, of subacidity, and of motor insufficiency. Butyric and lactic acids are the most common, both being present with about equal frequency, though the latter is more constant and thus more characteristic of cancer, though by no means pathognomonic. The following facts are of importance in regard to lactic acid in cancer of the stomach:

1. Its presence is not pathognomonic of cancer. The requirements necessary for the production of lactic-acid fermentation are merely these: subacidity, stagnation of food in the stomach, and a lessened digestion of albuminous foods. It may be present in the stomach in a case of intestinal obstruction, sometimes even in pyloric obstruction from benign growths, where the hydrochloric acid is diminished; also in severe gastritis, in atrophy of the mucous membrane, in fat-necrosis of the pancreas, in cardiac and renal disease, in gall-bladder carcimona, in pernicious anæmia, etc.

2. Lactic acid is introduced preformed into the stomach, under normal conditions, with the food. For this reason Boas recommends a test breakfast consisting of oatmeal and water, such a meal being free from lactic acid. It is prepared by adding a tablespoonful of Knorr's oatmeal, with a little salt, to one quart of water. This may be introduced at night into a previously washed out stomach, and the remains removed in the early morning. When cancer of the stomach exists, the bacilli present can form lactic acid, even after such a meal, more promptly than when lack of hydrochloric acid and a motor insufficiency are present.

3. Lactic acid is formed only in the absence of free hydrochloric acid. Even a little combined hydrochloric acid sometimes suffices to prevent lactic-acid fermentation, unless there also be a very marked atony.

4. In cancer of the stomach lactic acid usually appears early, often long before gastrectasis appears, though, according to Kuttner and Lindner, not before the tumor is palpable.

5. The presence of lactic acid merely implies three circumstances: (*a*) subacidity, (*b*) motor insufficiency, (*c*) lessened digestion of ferments, all three of which happen to occur most commonly in cancer of the stomach, though they may be present in other conditions.

Lactic acid, then, is not pathognomonic and may be entirely absent. Statistics show it to be present, however, according to Strauss, in ninety-one per cent. of all cases, according to Rosenheim in seventy-eight per cent., and in Kuttner's cases in sixty per cent.

The Microscopical Examination of the Contents of the Stomach.—This reveals at times the presence of blood cells and pigment, though these have no special significance *per se*. Particles of cancer formation are very rare in cancer. At the Royal Victoria Hospital this occurred but once in eighty-five cases in which the stomach contents were examined, but the event proved here of great value inasmuch as the diagnosis was otherwise in doubt.

The Boas-Oppler bacilli, which are long, thread like, non motile bacteria, occur chiefly where lactic acid is present, but are of no other diagnostic value so far as carcinoma of the stomach is concerned. Sarcinæ are uncommon unless free hydrochloric acid is present—therefore, as a rule, they are found only in those cases of cancer in which the neoplasm has been engrafted on a previous ulcer. It should be remembered, however, that the presence of sarcinæ is no proof against the presence of cancer. Yeast cells sometimes occur. Inasmuch as the digestion of proteid is delayed, meat fibres in abnormal quantities are usually found, while the starchy foods show more evidence of digestion.

Cancer of the Cardiac End of the Stomach.—In this condition dysphagia is a prominent symptom. At first there is a sense of the food stopping in the œsophagus, especially after solids have been taken, and liquids are ingested to assist in the deglutition of the solids. The symptoms are progressive, and water is now essential to carry down the solids, and discomfort and oppression follow. The food is then ejected by retching. Liquid diet alone is then possible. Later on, even very little of this, and still later none, can be taken without its being rejected.

There is regurgitation of much mucus, with or without food particles, and more especially at night. As already said, the deglutition sounds may be delayed or absent, though this is an unreliable sign. The passing of the tube meets with resistance and tubes of various sizes must be tried. It should be remembered that this resistance is not always a sure sign. However, the repeated finding of blood, commonly in a fresh state, on the tube after it has been withdrawn is a matter of grave significance, even if there are no signs whatever of stricture.

Cancer of the body of the stomach is associated with atrophy of the organ. This usually reveals a smaller stomach than normal, and its capacity becomes progressively less. The tumor is usually felt on the left side beneath the ribs. The passing of the stomach tube in such a case aids the diagnosis, and inflation either causes vomiting at once, or, at all events, no marked increase in the gastric tympany.

The *metastases* which occur in cancer of the stomach vary in size; they involve, of course, most commonly the glands and the liver. The thorax may be invaded, and the pleuræ, more especially the left; the lungs and the mediastinal glands may all be involved, as also, though more rarely, the peritoneum and the heart itself. There is practically no organ in the body which may not be secondarily involved by metastases, and under certain conditions these develop so much more rapidly than the original growth as to mask the primary seat of the disease. This is a most common occurrence where the liver is involved, or the peritoneum.

The metastases which occur upon the abdominal wall are of special interest, and attention has been chiefly called to them in recent publications by Dr. Osler. These occur subcutaneously as small nodules of various sizes, in and about the umbilicus, which itself may become very hard. The nodules may extend up over the chest, also over the area of the liver, and often their removal and examination constitute the necessary final step in establishing the diagnosis of carcinoma ventriculi.

Complications. Perforation of the stomach is not very common: most statistics agree in placing it at four per cent. There is usually a walled-off abscess cavity, which often progressively increases. Tracks may be made into the other viscera or the neighboring tissues.

Jaundice often occurs and may be due either to an obstruction of the main bile ducts, a secondary involvement of the liver, or, more rarely, to a simple catarrh of the common duct. As a rule, the jaundice persists when once present, though this is not always the case.

General anasarca, more or less slight in degree, may appear in the late stages of the disease. It is due to the cachexia and anæmia, or more rarely to a peripheral thrombosis.

Ascites may be present, and is associated usually with a cancer of the peritoneum, or an occlusion of the portal vein from the pressure of glands or the extension of the cancer into the part. The ascites may be a prominent feature, masking the original cause of the disease. When the ascites is associated with a cancer of the peritoneum, the fluid is usually hemorrhagic in character.

Multiple thrombi may occur, usually associated with marasmus, more rarely with occlusion caused by the neoplasm.

Diagnosis.—The earliest possible diagnosis is essential to a rational treatment of the condition, and a diagnosis should be established before a tumor is evident, either to palpation or to inspection. To establish such a diagnosis one must depend largely upon early evidences of functional disorder. It must be remembered that there is no single pathognomonic sign of cancer of the stomach. The disease of course may be latent, but the absence of gastric symptoms is an important negative sign. When the gastric signs are present and no tumor is evident, one must rely upon the age, the history, hæmatemesis, emaciation, gastrectasis, the chemical signs in the stomach contents, etc. When the tumor is palpable its location must be determined to be gastric, and this fact must be weighed in connection with the history and the general features, above described.

In the *differential diagnosis* one must consider mainly: (1) Those diseases in which hydrochloric acid is diminished or absent, and in which a tumor is not evident upon physical examination; (2) those general diseases in which the gastric evidences of disease are unsatisfactory, but in which the general signs warrant the suspicion that there is a latent gastric carcinoma; (3) the necessity, in the cases in which a tumor is present, of differentiating between (*a*) one which is located in the stomach and (*b*) one which is located outside that organ, in the immediate neighborhood.

1. Diseases with diminished or absent hydrochloric acid. These are mainly (*a*) chronic gastritis, (*b*) atrophy of the mucous membrane, and (*c*) gastric neuroses.

(*a*) Chronic Gastritis. Here the course and duration of the disease are important. The insidious onset with remissions and exacerbations, the local rather than the general features, the fact that hydrochloric acid is not always completely and permanently absent, and the probable cause (alcohol, etc.), all may be placed against a history in which there has been a previously healthy digestion with an unexpected and unexplained dyspepsia, not relieved by diet or drugs; with a probable hæmatemesis, severe general signs, and stomach contents which show persistent and progressive diminution of the hydrochloric acid and the presence of more or less lactic acid. Difficulties indeed arise where the gastritis is accompanied by atrophy of the mucous membrane and where the course is rapid and characterized by emaciation. Vice versa, it must be remembered that cancer sometimes develops slowly, and only with a mild dyspepsia.

(*b*) Atrophy of the Mucous Membrane. This may be associated with pernicious anæmia, with the terminal stage of a chronic gastritis, with achylia gastrica, with benign pyloric stenosis, or with cancer elsewhere.

In pernicious anæmia the nutrition is usually maintained, and there is an absence of hæmatemesis, gastrectasis, lactic acid, etc. The blood-changes, too, in pernicious anæmia are, as a rule, more marked than are those which occur in cancer of the stomach, though at times, it is true, the conditions of the blood may be incidental in each case. As a rule, however, there are more nucleated red cells of the blood, the poikilocytosis is greater, the color index may be higher, and there is more likelihood of the presence of megaloblasts when pernicious anæmia is present. Exacerbations and remissions too are more apt to occur in pernicious anæmia than in carcinoma.

Chronic gastritis has already been considered.

Achylia gastrica, considered by Einhorn and some others as an independent disease, implies a total absence of gastric juice. It is not associated in any way with cachexia or with progressive emaciation. The general condition of the patient is usually good, the digestive power excellent, even when there is no motor insufficiency, and examination of the stomach contents does not necessarily show the presence of lactic acid. More probably, as many suggest, achylia gastrica is merely a symptom associated with some other primary disease, such, for example, as cirrhosis of the liver. (Such a case has come under my personal observation.)

Benign pyloric stenosis, *vide antea*.

Cancer elsewhere, *vide infra*.

(*c*) Gastric Neuroses. In gastric neuroses in elderly people there is at times considerable difficulty in arriving at a proper diagnosis, though as a rule the general condition of the patient, frequent examination of the stomach contents, and the course of the disease soon lead one to a conclusion in the right direction. In such cases, as already mentioned, one must consider the age of the patient, the history, the presence of hæmatemesis, gastrectasis, lactic acid, etc., as well as the effect of treatment, both general and dietetic.

2. Those general diseases in which the gastric evidences are indefinite, but in which the general signs lead one to suspect a latent gastric carcinoma.

I have seen, for example, such difficulties arise in cases of suspected Addison's disease in which the general malaise, progressive weakness, dyspeptic signs, and general condition aroused a suspicion of the possibility of latent gastric cancer. As a matter of course, valuable aid may be derived from the examination of the stomach contents, where possible, and from a proper examination of the mucous membrane for the presence or absence of the usual pigmentary changes which accompany Addison's disease. To this may be added the injection of tuberculin, a reaction to which would render the presence of Addison's disease somewhat more likely.

3. The differentiation between (*a*) gastric and (*b*) non-gastric tumors calls for a careful weighing of the symptoms and signs presented and for a determination of the exact situation of the tumor.

The gastric tumors must be mainly differentiated as to their nature and situation. The signs and symptoms accompanying cancer of the cardiac end of the stomach and of the body of the stomach have already been mentioned (*vide antea*). As regards the nature of a tumor of the pylorus, there are four possibilities to be considered: It may be (1) a malignant growth; or (2) a scarred ulcer of the pylorus with stenosis; or (3) a simple hypertrophic stenosis of the pylorus; or, finally, (4) some other form of benign tumor, such as lipoma, fibroma, etc.

The symptoms connected with a cancerous growth of the pyloric end of the stomach have already been sufficiently considered. A scarred ulcer of the pylorus can be diagnosed as such only by the previous history of ulcer and especially of hemorrhages from the stomach, and by the finding—as happens in nearly all the cases—of free hydrochloric acid in the contents of the stomach. In other respects there are the usual signs of motor insufficiency associated with any pyloric obstruction, but there is not, as a rule, the same degree of wasting of the gastric muscle wall. Unless the general condition of the patient has suffered very greatly from malnutrition, the muscle wall remains hypertrophied for a great length of time, and peristalsis and anti-peristalsis may very frequently be seen even in spite of extreme dilatation.

The vomiting occurs, as in other cases of motor insufficiency with obstruction, at long intervals, is very copious and explosive in character, but as a rule, in contradistinction to what is observed in pyloric cancers, the proteids are well digested and the starches more or less unaffected.

Hypertrophic stenosis of the pylorus is usually slow in growth. It is very often congenital, and there is a history of many years of gastric symptoms without evidence of metastases; there are intervals, too, of good digestion, and the tumor which is found is usually smooth, not large, without adhesions, and therefore very movable.

Examination of the stomach contents will show the presence of hydrochloric acid and the absence of lactic acid.

The presence of some other form of benign tumor is rather to be inferred than accurately diagnosed. When it causes obstruction, the symptoms and signs resemble very much those of hypertrophic stenosis.

Growths Located Outside the Stomach.—The tumors simulating gastric growths, but existing in reality outside the stomach, are mainly:

1. The pancreas, either normal or pathological. When normal it is usually found deeply situated in the median line, fixed and immovable with respiration, and absent upon inflation of the stomach. When it is diseased, and especially when it is the seat of a cancerous growth, one may find clayey, fatty stools, even when there is at the same time no jaundice. Jaundice may, however, be present from pressure of the growth upon the common duct. The portal vein may be pressed upon and the resulting obstruction may give rise to ascites. There may also be glycosuria, and as a rule the course is a rapid one.

2. Tumors of the transverse colon. These usually give evidence of some degree of intestinal obstruction; the stools may be bloody. Examination of the stomach itself by test meals and inflation shows the absence of gastric disorder.

3. Tumors of the gall bladder are situated in their appropriate place, are somewhat movable, and may by pressure upon the surrounding ducts cause early jaundice. At times, however, the differential diagnosis is extremely difficult. While there need be no motor insufficiency, yet adhesions in the neighborhood of the gall bladder tumor may cause pyloric stenosis and certain signs of gastric cancer. The absence of respiratory mobility may suggest a gastric cancer rather than one of the gall bladder; but a test meal, when possible, will usually reveal the absence of the functional and chemical signs of gastric cancer.

4. Cancer of the duodenum. Here the difficulties are great indeed; it may be impossible to diagnose the true condition. One may have diminution or absence of hydrochloric acid. Lactic acid, on the other hand, may be present, as indeed may most of the other signs of gastric cancer.

5. Omental and peritoneal tumors, whether of a cancerous or of a tuberculous nature, are apt to be confused with cancer of the body of the stomach. In such cases one usually observes that these tumors are not mobile with respiration. The other important evidence of the nature of the disease is furnished by the examination of a test meal. It is especially necessary in such cases, however, not to omit an examination of the rectum. When the peritoneum is tuberculous, the subjects are usually young; there are fever, a longer course of the malady with exacerbations and remissions, and a reaction to tuberculin.

6. Cancer of the liver. This is usually secondary, and less easily fixed with expiration than are tumors of the stomach. A satisfactory means of differentiating is, where possible, to place the hand above the tumor. Then, if the liver can be felt still higher, the tumor is probably gastric; at all events it is not hepatic. The same is true if with inflation of the stomach the tumor alters its position. When the cancer of the liver is primary, the liver becomes rapidly large; jaundice is early and pronounced. The gastric signs are slight or absent and there is no hæmatemesis nor gastrectasis. Moreover, the usual signs after a test meal are not found in the contents of the stomach.

Other conditions which may simulate a gastric tumor are aneurism of the abdominal aorta, swollen glands about this artery, a movable kidney, and enlarged spleen, the last simulating a cancer of the fundus.

Prognosis.—The prognosis in nearly all cases of carcinoma is of extreme gravity. There are very few cases on record in which treatment has effected a cure. All medical treatment is purely symptomatic. Surgical treatment can only be of benefit by complete resection, and this can only be effected in those cases which are diagnosed extremely early. For this reason operation upon cases of carcinoma ventriculi is rather discountenanced by many, and Fitz regards the indiscriminate operation upon cases of carcinoma as of the utmost harm to the patients, causing no relief to the symptoms and only hastening the lethal termination.

Exploratory Laparotomy.—This is to be considered inadvisable where the cancerous nature of a gastric tumor is undoubted, or where the glands are secondarily involved, or other metastases are discovered. Only in doubtful cases, in which one feels sure from the general and local symptoms and signs that a progressive, slowly developing malady of the stomach is present, is one justified in making an abdominal exploration. Such an operation also should only be done with the expectation of carrying out still more radical measures, should the exploration afford any sure indication of its necessity.

In such conditions resection follows an exploratory laparotomy only when the pylorus or a small portion of the lesser curvature is alone involved. A good general condition of health, moreover, is essential to such an undertaking. Obviously, therefore, very few cases indeed ever gain benefit from radical treatment by the surgeon's knife.

Treatment.—This is both surgical and medical. The only rational treatment, so far as cure is concerned, is surgical. But in this respect a proper judgment in regard to the selection of cases for operation is of paramount importance.

The rational surgical treatment depends entirely upon the early diagnosis and the radical extirpation (resection) of the whole cancerous tissue.

Resection.—This is commendable only for cancers of the pylorus, or for more or less circumscribed cancers of the lesser curvature. There must be no adhesions to surrounding parts and no metastases. The general strength of the patient must be in a fair condition, and a certain amount of good motor power is also essential to a good result, in order that one may have thereafter a proper digestion. Without a good motor power the already diseased mucous membrane functionates badly, the undigested food remains too long in the stomach, and the previously existing suffering from dyspepsia continues.

Rosenheim claims to have shown that a motor insufficiency under certain conditions may be cured or much improved by the resection of a cancerous growth.

The failure to make an early diagnosis is the chief cause of failure of resection. In an overwhelming majority of cases resection is done too late and the results are correspondingly bad.

Gastro-enterostomy.—This is performed only when resection is not feasible, and is to be considered merely as a palliative measure. Even this should be undertaken only when the stenosis is so extreme as to render the combined use of lavage and gastric feeding useless to maintain an ordinary nutrition of the patient. The nature of operations indicated in the treatment of gastric cancer is mentioned in the article on the surgery of the stomach.

Gastrectomy is recommended only for cancer of the cardiac end of the stomach, and the operations recommended by Witzel and Frank would appear to be those most commended.

Statistics as to the results of operations vary very greatly, and the recent communication of Fitz should do much to aid the judgment of surgeons in the proper selection of cases for operation. His after-history of cases upon which laparotomies had been performed tends to show that in the majority of instances patients have become rapidly worse rather than improved by the treatment.

The Medical Treatment.—This concerns, of course, chiefly the inoperable cases, or those cases which, having been operated upon, require still further treatment for a cure.

Inoperable cases must be treated medically for various reasons. One is unable perhaps to resect on account of the advanced condition, or a gastro-enterostomy is not yet required; or, it may be, that a resection is difficult or inadvisable on account of the cachexia or metastases present; or, again, through refusal of the patient to allow an operation to be performed. And lastly, one must treat cases after a gastro-enterostomy has been performed, when the neoplasm and the symptoms reappear *de novo*.

The main treatment is dietetic. The diet, however, should not be too strict, and one must go rather upon general principles than upon any definite lists of foodstuffs. Inasmuch as one can but alleviate rather than cure, the patient's own tastes should be consulted even when spices and other apparently harmful foods are desired. The meals should be small and frequently given, rather than large and few in number. On account of the deficient hydrochloric acid, meat should be limited in amount. It should be finely divided and free from cartilage and other substances difficult of digestion. White meats are to be preferred; chicken, game, pigeon, veal, and beef in small quantity, and calves' brains and fish, are often well borne. All these proteid foods should be followed, after meals, by small quantities of hydrochloric acid (unless, of course, there is hyperacidity from a cancer engrafted upon an old ulcer).

One may give, as recommended by Fleiner, sauces containing hydrochloric acid, his special one consisting of: Beef juice, ℥ ss.; warm water, ℥ iij., to which has been added ten drops of dilute muriatic acid. Meat jellies and somatose are well borne.

Vegetables may be given in relatively large amounts, though one should avoid those which are coarse and indigestible; those, therefore, with shells, skins, fibres, etc., as well as those which are fermentable. The most suitable of all are perhaps spinach, artichokes, beans, peas, and carrots.

Bread may be allowed, as also gruels and vegetable soups, particularly rice, macaroni, barley, tapioca, sago, and oatmeal.

Milk containing nutrose, eucasin, or plasmon may also be taken, while buttermilk, kephir, and kumyss are likewise often well borne. The fats are best supplied by butter.

For beverages, apart from those mentioned above, one may take the light wines, weak brandy and whiskey. All fluid should be limited in amount because of the motor insufficiency. There is often great thirst because the tissues are dry and hot, and water may often relieve this condition. When the condition is extreme, it may be well to give daily enemata of plain water, one-half to one pint at each injection.

Lavage is the best means of treatment that we have in cases of inoperable carcinoma of the stomach. It helps to stimulate the appetite and the secretions; it washes away food remnants and prevents fermentation. One may use either plain water or water to which salicylic or boracic acid has been added. The lavage is performed in the morning, and if the condition be of an aggravated character a second lavage may be done in the evening.

Medicines.—No medicine is of any great value. Orexin in doses of five grains may help the appetite, as also may an infusion of condurango bark. One finds that alkaline mineral waters before meals sometimes stimulate the secretions, while hydrochloric acid after meals helps proteid digestion.

For the vomiting, especially of blood, rest to the stomach is essential. Nutrient enemata may be given, and then careful feeding by mouth may be begun with small quantities of fluid. For the ordinary vomiting lavage is the best form of treatment.

Diarrhœa should be treated by a proper diet where possible, and by the use of lavage to remove irritating substances which are the probable cause of the condition.

For the constipation, aloes, rhubarb, and cascara are the most effective remedies. Enemata should be given when the condition is aggravated, but this should not be persisted in too long. Authorities differ as to the use of saline purgatives, and doubtless in individual cases their use will have different effects.

For the pain, wet compresses upon the stomach, lavage, and the use of spirits of chloroform may be of value, and it is only in the extreme cases that morphine should be employed.

X. PYLORIC STENOSIS.

There are two main conditions—malignant pyloric stenosis (cancer of the stomach, *q.v.*) and benign pyloric stenosis.

Benign Pyloric Stenosis.

1. *Congenital Atresia.*—This is rapidly fatal. Soon after birth there is uncontrollable vomiting, even before food and drugs have been given. Sometimes there is a tiny opening only into the duodenum, and death is then more gradual and accompanied by inanition. The stomach may be hypertrophied in consequence.

This atresia may exist in the duodenum, and, if it be situated high up, the symptoms will then be, to all intents and purposes, similar to those mentioned.

2. *Hypertrophic stenosis*—that is, hypertrophy of the fibrous and muscular tissues; this develops slowly and lasts for years.

3. *Foreign body.*

4. *Benign tumors*, especially fibroma (polyp).

5. *Cicatrized Ulcer.*—Such ulcers are of various kinds.

6. *Pressure from Without.*—A movable kidney, as in the case of Dr. Bramwell's patient (*vide British Medical Journal*, October 19th, 1901), may be the cause of such pressure. Adhesions and fibrous bands, such as result from perihepatitis and from cirrhosis of the liver, as in the case of F. H. Murdoch's patient (*vide American Medicine*, January 11th, 1902), may also cause gastric stenosis through pressure.

7. *Duodenal obstruction*, especially when associated with great laxity of the abdominal walls, is competent to cause pyloric stenosis by drawing upon and twisting the horizontal portion of the stomach.

8. *Spasm of the Pylorus.*—This is mentioned, among causes, by Sir William Bennet (*British Medical Journal*, February 3d, 1900).

Symptoms.—The earliest signs of all are shown when dietetic errors, chiefly as regards the quantity of food, cause general gastric distress after meals. Soon afterward, however, other symptoms develop. The main signs in both the early and the late stages are pain and vomiting.

The pain at first is more of an indefinite gastric distress, which develops only after meals. This is followed in one or two hours by vomiting of solids which are excessively acid. This vomiting gives relief. Then, after a variable period of hours, days, or weeks, the symptoms recur and with exacerbations. The pain is greater, more frequent, and may be cramp-like if already hypertrophy of the gastric muscles has occurred. Later, the pain becomes more or less continuous, and is associated then with increased peristalsis, though it may in part be due to the hyperacidity, hypersecretion, fermentation, or an ulcer if present. In the later stages, when there is retention of food, the pain is often marked at night.

Ordinarily the vomiting increases synchronously with the pain. When the muscles are hypertrophied the vomiting which accompanies the cramps is more explosive; it may occur at any time and not merely after meals, and often there may be an interval of a day or more between the attacks. When the diet is not regulated and motor insufficiency increases to a great degree, the vomiting becomes less frequent (once every few days perhaps), more copious, and shows much evidence of fermentation.

The vomitus, on standing for a short time, separates into three layers, the lowest consisting of more or less digested chyme, the middle layer of turbid fluid, and the uppermost of frothy mucus and particles of undigested food.

With these two cardinal symptoms of pain and vomiting there is, in the early stages, a good appetite till fermentation becomes marked. On the other hand, thirst, which is at first not a prominent symptom, becomes distressing with increase of the motor insufficiency.

To the above symptoms loss of weight and strength should be added.

The general constitutional symptoms in such cases affect the heart action, which may be irregular, intermittent, or more rapid than normal. The movements of the diaphragm are limited; there are neurasthenia, anæmia, cold extremities, weak and flabby muscles, a dry scaly skin, progressively developing cachexia, marked constipation, and a diminished quantity of urine.

The Physical Signs.—The early stage may show nothing or merely a prominent epigastrium; peristalsis, though slight, may be visible early. There may be more resistance than normal over the area of the stomach, which may give a more cushion like sensation on palpation. If the abdomen be thin and flabby, a tumor may already be felt at a comparatively early stage.

Later, when the obstruction is more marked, one is more liable to see peristalsis, either spontaneously or after stimulation, as by flicking the abdomen with the fingers or an instrument. Succussion may be obtained during the period when gastric repose should exist, and a tumor may now be still more evident.

When retention has occurred the above signs will be still more marked and succussion may be obtained at any time during the twenty-four hours. The abdomen is prominent, especially when the stomach is filled with food or gas.

The Tumor.—The pylorus and the regio pylorica, normal or abnormal, are very often movable, and may be found in a great variety of positions. A tumor of this part, therefore, may be felt in various positions unless adhesions be present; and one must decide between a neoplasm, a hypertrophy of the pylorus, and a scarred ulcer. Or, again, the ill defined mass may be due to an inflammatory exudate, etc., around the outside of the pyloric ring.

The patient should be examined lying on his back. The stomach should be empty and the bowels evacuated. Especial care should be taken to look for the descent of the tumor with inspiratory efforts, as often happens when the tumor is adherent to the liver. Under such conditions the origin of the tumor may be hard to determine, unless one can dip the hand down between the tumor and the liver itself.

At other times the tumor may not only be felt in various parts of the epigastrium and to the right of the median line, but it may even be visible as a projecting lump above the general plane of the abdomen. It sometimes is found below the navel; or, again, because of adhesions, it may be displaced upward, beneath, or next to the liver.

At still other times the tumor is to be felt or seen only on inflation of the stomach with gas. A tumor in the neighborhood of the pyloric region, which upon inflation is displaced to the right and downward (more rarely upward), and which returns to its original position when the stomach is again empty of gas, is undoubtedly a tumor belonging to the pylorus.

The functional signs are more or less characteristic only during the time when stagnation or retention occurs. While the solids of a test dinner are delayed the fluids seem often to pass through the pyloric region much more rapidly than is usually the case with idiopathic gastrectasis. In this case the total acidity is usually high, from the presence of either lactic or hydrochloric acid. With hydrochloric acid there are usually the yeast fungi and perhaps acetic acid, while the sarcinæ ventriculi are also commonly present.

In benign obstruction hyperchlorhydria is the rule. When organic acids are present, malignancy is suggested.

Differential Diagnosis.—Cases are not usually recognized before stagnation has become marked. Suspicion should be aroused when there are recurrent attacks of indigestion, especially with pain and vomiting, in patients who have previously suffered from ulcer, gall-stones, etc.

When the motor insufficiency is advanced, we must decide whether this condition is due to an obstructed pylorus or is idiopathic. (For this differential diagnosis see the paragraph on motor insufficiency.)

From *supersecretion* the diagnosis is not difficult if the stomach can be thoroughly washed out at night and its contents examined again on the following morning. In the fasting stomach no contents should be found when obstruction alone exists; but, if supersecretion be present, more than 30 or 40 c.c. of fluid (which is probably hyperacid) can be removed.

It is by no means easy to decide whether the obstruction is pyloric or *duodenal*. Duodenal obstruction is usually associated with gastroptosis or with cancer, with pressure exerted by a benign tumor, with scarred ulcer, local peritonitis, gall-stones, or some congenital abnormality. If the obstruction be *above* the common duct, it cannot be differentiated from pyloric stenosis. Gastroptosis may be the cause, but it can only be suspected by exclusion. Obstructions *below* the duct are suspected when more than a normal quantity of bile is in the fluid vomited, and when it is found at an early stage of the vomiting.

To decide whether the obstruction is malignant or benign is sometimes easy, at other times quite impossible. The following table may be of some assistance in this respect:

	Benign.	Malignant.
History	Ulcer, toxic gastritis, etc.	
Tumor	Smooth, as a rule	Nodular, hard.
Secretions	Hydrochloric acid normal or in excess.	Hydrochloric acid usually absent or amount small.
	Lactic acid, usually absent	Usually present and with bacilli.
	Butyric acid, usually absent.	Butyric acid common.
Gases	SH_2	SH_2 uncommon.
Bacteria	Sarcinæ, long present	Absent or soon disappear when lactic acid is present.
Age	Any age	Above 20.
Course	Rapid	More rapid and progressive.
Therapeutic measures.	Rectal feeding benefits	Rectal feeding does not cause benefit.
Metastases	None	May soon appear.

Cancer of pancreas and gall bladder seldom diminish gastric secretion till cachexia is present.

Diagnosis of the Nature of the Benign Obstruction.—It may be (1) cicatricial tissue, the result of a *toxic gastritis*, and this should be revealed by the clinical history.

(2) *Congenital atresia or stenosis.* This should be suggested by the age of the patient, by the onset and the course of the disease, and by the general signs and symptoms.

(3) *Hypertrophic or hyperplastic stenosis,* which may be congenital or acquired. As a rule this is a developmental hypertrophy, but it may be due to spasm of the pylorus from various causes, or it may be the result of a congenital narrowing of the lumen and a secondary hypertrophy of the muscles. The lumen varies in size. The increased tissue is muscular and fibrous, and the mucosa shows often a catarrhal inflammation.

Congenital cases are rare (see *British Medical Journal*, April 28th, 1898). Less than fifty cases have been recorded, and they occurred usually under four months of age; they have been observed more often in male children, and the main signs of diagnosis are as follows:

1. Duration from infancy.
2. Persistent vomiting from no apparent cause, nor with any other sign of indigestion; occurring at variable times after food, or only after several meals have been taken; and sometimes ceasing temporarily with careful dieting and lavage.
3. Emaciation.
4. Constipation.
5. A palpable tumor.
6. Visible peristalsis.

In the acquired cases there is usually a history of persisting gastritis. Examination of the abdomen shows a smooth, non-adherent, regular tumor. The late course is rapid, and unless operation be performed a fatal issue is bound to ensue.

The degree of obstruction, as regards compensation, stagnation, or retention, is easily told by the ordinary tests for the motor power. The quantity of the urine, moreover, in the twenty-four hours, may aid somewhat in estimating the degree of obstruction, provided there be no great perspiration, diarrhœa, vomiting, or renal disease. The course of the disease is another guide in this particular.

The prognosis, unless operation is performed, is always grave and in proportion to the degree of obstruction and the cachexia which has developed.

The TREATMENT is both medical and surgical.

The *medical* treatment is symptomatic, not curative, and it is useful when operation is otherwise contraindicated or impossible.

The *dietetic* treatment: In the early stages there should be no excesses and the food should be finely divided. There should be a moderately dry diet consisting of albuminous foods, chiefly meat, poultry, fish, eggs, milk, a few cereals in purée form, and ordinary vegetables in moderation; and one should avoid coarse irritating solids and fermenting liquors, such as beer. The food should be given in small quantities, and nothing that is starchy or sweet should be permitted if hydrochloric acid be abundant. In some cases it is best to give three small concentrated meals. When vomiting persists it may be necessary to give nutrient enemata.

The *mechanical* treatment is to be used in the later stages. Rest is essential. Lavage should be thoroughly performed, either in the early morning or before the evening meal.

The three guiding principles are, first of all, that the stomach should be empty before each meal; second, that the food must be finely divided, readily soluble or easily rendered fluid, and not apt to disturb the secretory or motor functions; and, third, the diet must be varied and sufficient to support or improve nutrition (Van Valzah and Nisbet).

The *medicinal* treatment: For the persistent vomiting rectal feeding and, if pain persists, atropine in doses of gr. $\frac{1}{150}$ hypodermically, may be used. Morphine may be required, though codeine may cause less nausea and be equally effective.

For the constipation, enemata of soapsuds and of oil should be used, or glycerin suppositories may be tried. Purgatives, especially drastic purgatives, should be avoided, and even the mild purgatives should be given as infrequently as possible.

The *surgical* treatment: Many operations have been devised and as quickly rejected. Loreta's digital divulsion is inefficient and therefore not to be recommended.

Pylorectomy is not indicated in benign obstruction when a gastro-enterostomy can be equally well done, as the latter gives eminently satisfactory results, and is in all probability the less dangerous operation.

The two operations which have found most favor are the gastro-enterostomy and the pyloroplasty, as suggested by Heinecke and Mikulicz.

The operative treatment, however, in this condition has been considered in the article on the *Stomach and Œsophagus, (Surgical)*. The indications for operation, therefore, are mainly these—when the obstruction is continuous, and when the patient cannot be successfully nourished by other means, then operate.

XI. SIMPLE TUMORS.

Simple tumors play a very small part in the diseases of the stomach. There are several conditions which, by producing a tumor in its broadest sense, may cause some difficulty in diagnosis. Of these one may mention:

Tubercle in the stomach is excessively rare. Hale White in "Allbutt's System" reports five cases of tuberculosis in the stomach, in one of which, in a male aged seven years, there were found enlarged and caseous lymphatic glands at the lesser curvature.

Syphilitic gumma in the stomach is less rare, as first shown by Chiari, of Prague.

Phlegmonous gastritis, especially when going on to acute abscess, produces a mass within the stomach. This is extremely rare and generally rapidly fatal in several days. (*Vide* section on Gastritis.)

Hypertrophic stenosis of the pylorus is common in adults and produces tumor and dilatation. A series of forty-five cases in infancy has been reported (Rolleston and Crofton-Aikens), mostly in children under four months, with very few recoveries. Six were operated upon and one was cured. (*Vide* section on Pyloric Stenosis.)

The cicatrix following ulcer, though producing no swelling, may convey a sense of hardness to the touch. Such a cicatrix, although not classed among the new growths, is one in reality.

One form of tumor simulating gastric disease may be referred to, viz., preperitoneal *lipoma*. A young man, complaining only of moderate diarrhœa during five months, showed, on inspection of his abdomen, a small tumor in the epigastrium, discoid, slightly lobulated, and 3.5 cm. in diameter. It was too superficial to be elsewhere than in the abdominal wall, and did not in the slightest degree rise and fall with respiration. It was in fact a lipoma epigastrica. In the surgical department Dr. Archibald pointed out that one such case, which had come to operation, showed that the lipoma, originating in the preperitoneal fat, had become adherent to the omentum, and had so dragged on it as to cause the symptoms of which the patient complained until the operation removed the growth.

A full account of these herniæ is given in the "Handbuch der praktischen Chirurgie," Bd. iii., Th. t, where it is shown that the lipoma originates in the preperitoneal fat and grows forward, ever stretching more and more an opening in the lattice-work between the recti muscles, until a firm ring is formed, or several, up to four (Berger), through which as many herniæ are forced. On cutting down on such a lipoma one finds that it envelops a funnel-shaped cord of peritoneum or true sac, which is often empty, but which more frequently contains omentum adherent to the hernial sac. Rarely, the sac contains transverse colon. In 10,000 herniæ Berger counted 137 cases of hernia epigastrica (1.3 per cent.), of which 120 were in males generally with other herniæ, and mostly in elderly spare people. More than half the cases were traumatic in origin, sometimes a muscular strain, sometimes a direct blow on the abdomen, being the exciting cause. Of interest to us are the many "gastric" symptoms caused by these apparently innocent tumors, viz., violent pain, tearing or boring in character, in the gastric region, belching of air and vomiting, distention, and difficult bowel movement, dyspnœa, palpitation, faintness, diarrhœa.

The symptoms may eventually assume a nervous type (hypochondriasis), with loss of flesh. These symptoms suggest the stomach, but only one case is on record and this showed that a part of the stomach was in the sac. In fact, almost all the above symptoms have been reported in cases in which no part of the gut was directly involved, the sac containing only fat lobules together with vessels or nerves. The commonest content of the sac, then, is omentum; less commonly, part of the transverse colon. The symptoms are explained either by traction through the omentum on the colon and through the gastrocolic ligament on the stomach, or by traction and bruising of nerves. In some cases the lipoma is not in connection with peritoneum, but generally it is attached to a large diverticulum of peritoneum which embraces from time to time parts of the omentum, or of the bowel, or both. Careful palpation will reveal an irregularity in the linea alba and the pressure of a hazelnut-sized soft tumor, slightly tender perhaps, which gives way on deep pressure, leaving a pit and a distinct gap in the abdominal wall. Rarely, one can at the height of the paroxysmal pain feel a tension in the tumor, which is relieved by suitable posturing. The symptoms are generally referred by the patient, and indeed by the physician, to other causes, *e.g.*, gastric ulcer or gall stones. The case referred to above as having been operated on is reported in full by Roth in the *Archiv für klinische Chirurgie*, Bd. 42. After his accident the patient continued to have frequent paroxysms of incapacitating symptoms for seven years, during which time he suffered much of many physicians, and of bath and "cure institutions," until he sought a surgeon, who cut down and found the lipoma enveloping a funnel-shaped tube of peritoneum, to which a part of the omentum was adherent. It was radically treated and the ring accurately sutured. Fourteen days later the patient felt well and had remained so up to the date of the report.

Another case, in a male aged eighty-three, was seen post mortem; in this case the lipoma was no larger than a hazelnut, but the symptoms (pain, nausea, vomiting) had been prominent. The mass of fat was found adherent to the suspensory ligament of the liver, which, when drawn on by the lipoma, pulled the stomach down, producing, by constriction, a typical hour-glass shape in that viscus.

The true simple tumors in the stomach recorded are:

1. *Fibroma*—a congenital fibrous thickening at the pylorus, leaving a very small lumen—has been seen in the body of an infant five weeks old. Finkelstein reports several. These patients die within several months of birth.

2. *Fibromyoma*—very rare; it occurs up to the size of a pigeon's egg, and projects into the stomach. These tumors consist of unstriped muscle and fibrous tissue, sometimes pedunculated and in some cases multiple.

3. *Lipoma* has been very rarely described.

4. *Polyadenomata* are common and often numerous. Osler says one hundred and fifty were seen in one patient. They raise the mucous membrane into polypoid masses, the "polyadenome en nappe" of the French.

5. *Multiple cysts* in the wall of the stomach (and of the intestines) have been described by H. B. Anderson.

XII. FOREIGN BODIES IN THE STOMACH.

The question of foreign bodies in the stomach, apart from the perennial scares of the nursery, is a matter rather of the music halls and the footlights than of clinical import or medical literature. In the nursery children swallow small coins, buttons, and various hard objects of endless description. The more serious objects do not reach the stomach, being generally arrested at the level of the cricoid cartilage; while of those which reach the stomach the vast majority give no serious trouble, being passed by natural channels in due time. In most cases, then, especially when one has only the statements of surrounding children to go upon, the best treatment is a little judicious letting alone. Peabody, however, reports a case in which

FIG. 4547. Hair Bolus in the Stomach, Found at Autopsy. The specimen is preserved in the Medical Museum of McGill University, and mention of the case will be found in Osler's "Practice of Medicine," 1901.

a pin pierced the œsophagus and reached the heart, while Dock mentions an ear of barley reaching the liver. At an operation for appendicitis in the Royal Victoria Hospital Dr. Bell showed a large pin snugly embedded in the mucous membrane of the appendix. Music-hall artists do, apart from optical illusion actually swallow metallic objects, considering the plaudits of the gallery and an increased salary sufficient reward for their loss of internal comfort. The more experienced the performer is, so much the finer will be the collection which he makes,

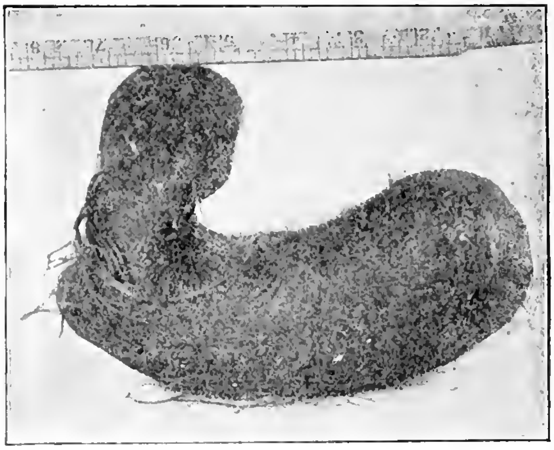

FIG. 4548.—Dr. James Bell's Case of Hair Bolus in the Stomach. Royal Victoria Hospital, Montreal.

and he need never feel that the loss of the treasures will be permanent, for at some period in his career his life will become intolerable, and he will by the aid of the surgeon recover the goods. In fact, every year one reads in literature, medical as well as lay, of several persons being admitted to hospital with slight, vague gastric symptoms. On opening the stomach a truly remarkable store of manufactured articles is revealed. Countless pins, nails, buttons, coins, false teeth, iron plate, buckles, and chains are among the favorite articles, while the knives or portions of other cutting instruments excite the greatest astonishment.

A medical friend assures me of having seen in the Dupuytren Museum in Paris a full-sized silver dinner fork which was found in the human stomach. It is well known that painters occasionally swallow spirituous shellac, which may harden and lodge in the stomach. In the Canadian Northwest there are Indians who, when suffering from lack of food, feel better with something in the stomach, and deliberately place there great pieces of caked earth.

Riegel mentions the fact that a stomach tube has been lost in the organ for long periods, and states that foreign bodies in the intestine may ulcerate into the stomach. Sarcina ventriculi has produced an obstructing tumor in the stomach (Riegel). The remarkable hair tumor in the stomach, common in cattle and swine, though rare in human beings, is well known. Osler, writing in 1901, states that there are only sixteen cases in the literature. He has made famous an example (Fig. 4547) of such in the McGill Medical Museum, Montreal. Such cases occur mostly in hysterical young women from fifteen years of age upward and in the insane. Several cases, however, have been reported in children who formed the habit of swallowing their own hair. One case is on record in which a young fair haired girl swallowed not only her own hair but also that of her black dog, and in her stomach was found a correspondingly variegated hair bolus. These bodies are puzzling, especially when only partially filling the stomach, and are generally overlooked or pronounced cancer. Of the 16 cases mentioned by Osler 9 were recognized only at autopsy, 7 were operated on, of which 6 recovered. The literature shows that, as a rule, there are masses of hair in the intestines also, and these commonly kill by perforating ulceration. A very remarkable case was reported (Montreal *Medical Journal*, February, 1903) by Dr. James Bell, in the person of a twelve year-old girl, who was admitted to the surgical wards of the Royal Victoria Hospital, November 13th, 1902, with a "tumor of the stomach," and complaining of vomiting and diarrhœa. She had had good health till January, 1901, when vomiting and diarrhœa were severe for ten days, and less so for the following three months. There was some pain in the lower part of the abdomen. The vomiting had no relation to eating, and brought up mostly frothy mucus. In May, 1901, she returned to school for a year (May, 1902), during which time she had fair health, with only occasional vomiting and diarrhœa. She then (May, 1902), however, had the same symptoms in very severe form, and left school. At this time a mass was felt, and was thought by a physician to be abscess of the liver. Through the summer of 1902 she was walking about, though showing some similar symptoms. Her appetite was very capricious; she took meals very irregularly and would never consent to eat much at a time. On admission, November 13th, 1902, she was a slight girl, weighing forty-nine pounds; temperature normal, pulse 144. In the position of the stomach there was a painless, hard mass, and a diagnosis of probable hairball was easily made. On November 17th, 1902, operation; abdomen opened in the median line, wound packed, and incision four inches long made in the anterior surface of the stomach, midway between the curvatures. The pyloric prolongation was hooked out and the mass delivered (Figs. 4548 and 4549). Some of the hairs were found to be eighteen inches long. A small detached mass was seized in the intestine. The stomach and the abdomen were closed without drainage. After operation some diarrhœa continued. The child was very intelligent at school, and she was known, three years previously, to break her hairs with her fingers, but was never seen to put them in her mouth. Mits were bound to her hands and the habit was apparently cured, for nothing was seen of it in the last two or three years. The hair in the stomach in this case is much darker than that on the patient's head; and the same fact has been noted by all previous observers. This is due to chemical action, the exact nature of which is a matter for theorizing. One can imagine, as Dr. Bruère points out to me, that some of the ample supply of sulphur in the keratin of the hair combines with hydrogen in the stomach to form sulphureted hydrogen, which latter, having a powerful affinity for iron, combines with the iron in the melanin granules occurring in and between the cells of the hair,

FIG. 4549.—Slightly Different View of the Hair Bolus Found in Dr. Bell's Case, showing a cast of the duodenum.

to form sulphide of iron. This sulphide may do the staining. Dr. Bell has kindly stated that after the operation (November 17th, 1902) occasional vomiting and considerable diarrhœa with fœtid stools persisted. On December 13th a hard mass was palpated in the right hypochondrium, and on December 15th the abdomen was reopened and a tear in the ileum found through which a tuft of hair protruded. The mass, when extracted, proved to be a cast, eight inches in length, of the intestine. On December 20th a third operation was performed and a new perforation was sewn with Lembert suture. On December 23d, at the fourth operation, the small intestine was found riddled with openings, and two inches of gut were removed and the cut ends were united by sutures. On December 26th a fæcal fistula established itself, and one hair came away in the dressing. At three more operations fresh perforations were found and closed. On January 22d a large opening was found, but the patient's condition prevented a resection. On January 29th it was found that sutures would not hold in the intestines. In March a resection was done and the divided ends of the bowel were united by a Murphy button, which has been passed since. Now (April 18th) there is no fæcal fistula, and the patient, after eleven operations, is apparently, on the high road to recovery.

XIII. DISPLACEMENT OF THE STOMACH.

In the fœtus, and in fact at birth, the stomach appears to be an ill-defined portion of the alimentary tract, or a mere loop, slightly dilated it is true, of the gut. At necropsy its limits are not readily made out, and in removing the organ in order to ligature its orifices and inflate the stomach, with the view of measuring its capacity or for teaching purposes, one is at a loss to know precisely where to place his ligatures. This is particularly true of the pyloric end, where the muscle is not yet concentrated into a sphincter-like mass as in the adult; while at the cardiac end one notes an absence of that expansion in the adult organ called the fundus. Furthermore, the entire stomach occupies a position much more nearly vertical than is the case in adult life.

Bearing this in mind, one is at times struck with the resemblance, in an abnormally placed adult stomach, to the fœtal form and position. At such a time one can think of a persistence of fœtal conditions.

Normally, the stomach is a large, flexible, hollow viscus, whose thin, mostly flaccid walls and more or less empty condition render it utterly unable to hold its own (position and form) against the many moving organs with which it is in immediate relation. It is ever completely at the mercy of the diaphragm. There is thus, accurately speaking, no one normal site for the stomach. It also falls a ready victim to pressure from an abnormally placed liver, spleen, or other abdominal organ, and has been seen dislocated by inflammatory disease or tumor in the pleura and the pericardium above, in the intestine below, in the gall bladder to the right, in the spleen to the left, in the abdominal wall to the front, and in the spinal column behind.

Physiologically, every demand on the stomach and every filling of it leads to a change in size and form; and the same holds for the intestine. There is thus a constant elbowing for room among the abdominal organs in the performance of their respective functions, and an equally constant accommodation to conditions of space on the part of each individual organ, especially the stomach.

One must think then of mere abnormal exaggeration of function in explaining some pathological displacements. Indeed, one finds the most typical dislocations in connection with what gives the greatest demands on the abdominal organs, namely, pregnancy.

Displacements of the stomach are (1) *congenital* and (2) *acquired.*

The *congenital* cases of medical interest or of any clinical importance are caused by two conditions, viz.: (1) Defect of the diaphragm, and (2) transposition of the viscera (thoracic and abdominal).

The *acquired* cases are comprised under:

1. Enteroptosis, or Glénard's disease.
2. Rupture of the diaphragm (traumatic).
3. True diaphragmatic hernia.
4. Descent of stomach owing to dilatation apart from general enteroptosis.
5. Displacement by corsets.

6. Displacement by neighboring disease.
7. Displacement resulting from pyloric obstruction by malignant disease, an ulcer's cicatrix, hypertrophic stenosis, etc.

Like most classifications, this is more convenient for teaching than rigidly accurate in application, for in nature its divisions occasionally overlap. This is true even in regard to the large divisions "congenital" and "acquired," for examples occur in which it is difficult to say to which class the case belongs, and one meets other cases in which he can definitely prove that the patient acquired by an exciting cause a pathological condition resulting in part from a congenitally inefficient organ. Such was true of a case, about to be related, of congenital defect of the diaphragm combined with true hernia.

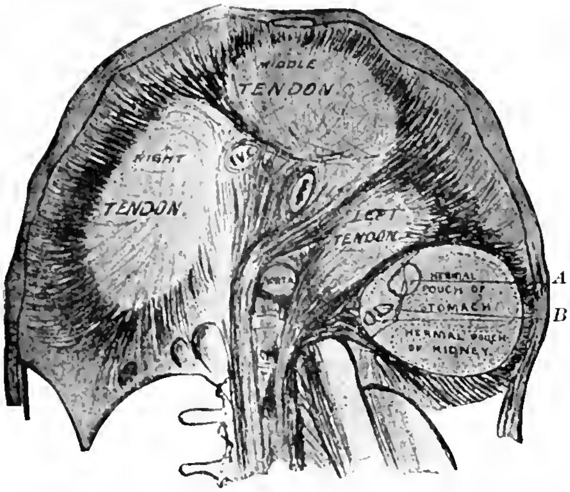

FIG. 4550.—Diagrammatic Representation of the Diaphragm seen from Below, showing the Position and Relative Size of the Hernia. *A*, Large, and *B*, the small communications between the thoracic and abdominal cavities. Over *A* and *B* is indicated the commencement of the omental overgrowth.

In connection with *defect of the diaphragm*, we have to distinguish between three conditions, viz.:

1. Absolute defect or congenital false hernia with free passage between the thoracic and the abdominal cavities. This is certainly extremely rare, almost undescribed, and of no clinical importance. One can suspect, however, that cases occur and are overlooked, since such a defect prevents any efficient establishment of respiration, thus killing at birth.

2. Acquired false hernia, or rupture of the diaphragm with protrusion of abdominal organs into the thoracic cavity, without, however, any hernial covering (peritoneum or thinned diaphragm). This is by far the commoner variety. Thus, of Leichtenstern's two hundred and fifty-two cases, two hundred and twenty-four were of the "false" type. It may be added here that any descent of thoracic organs into the abdominal cavity in such an accident is not known to occur. The vast majority of these cases are acute, following obvious violence or excessive muscular effort or strain. Thus they form a group of traumatisms, and their treatment, if any, is surgical. This is rendered all the more unsatisfactory, as exact diagnosis is generally difficult and often impossible. All abnormal openings in the diaphragm are much more common on the left side (five or more to one), owing chiefly to the liver's standing sentinel on the right side.

The organs most frequently displaced are the stomach and the transverse colon; next come the small intestine, spleen, left lobe of the liver, and pancreas. The displaced stomach gives the more prominent symptoms. The abdomen may be depressed while the affected part of the thorax may be prominent. Over a considerable area the breathing sounds are diminished or absent, and this area varies, under percussion, with the contents of the stomach. If the stomach contains mostly air the condition will simulate pneumothorax. The chief symptom is dyspnœa, generally with vomiting.

3. True diaphragmatic hernia, in which there is thinning of the diaphragm so that the abdominal organs, covered by a hernial sac of diaphragm or peritoneum, or both, protrude into the thoracic cavity.

This is the rarest variety, only eleven per cent. of Leichtenstern's two hundred and fifty-two cases being true herniæ. For the account of a remarkable case of true hernia, with displacement of the stomach, the reader is referred to the Montreal *Medical Journal*, August, 1895. "A Case of Diaphragmatic Hernia," by F. M. Fry.

Transposition of the Stomach.—One meets with displacement of the stomach in connection with transposition of the viscera in general, even more rarely than that due to defect of the diaphragm.

It is in the complete cases that one looks for displacement of the stomach, *i.e.*, a stomach whose cardia is to the right and the pylorus to the left. Arneill (*American Journal of the Medical Sciences*, November, 1902) gives interesting reports from experienced American clinicians, some of whom have never met with a case, while others have seen several only in many years. Arneill adds five cases seen since 1897, in which partial notes on the abdomen are given, and in one of which he mentions that the stomach, on inflation, was found transposed.

A case of complete transposition has recently come to Dr. Martin's notice at the Royal Victoria Hospital, Montreal. The skiagram of the case which I had taken shows the displacement of organs very well, while examination of the stomach by the ordinary methods showed its transposition.

Displacement by corsets is familiar, and we do not purpose enlarging on the widespread evils due to this cause. Certain it is, however, that it plays a great rôle in limiting the functions of the stomach and other organs, chiefly by compromising circulation and muscular action, thus leading to congestion and weak muscles with the resulting ills. The changes in the stomach, noted particularly by English observers, are a more vertically placed organ, narrowed and elongated. Treves insists on having seen these changes in patients in whom compression by corsets did not exist.

Displacement by neighboring disease calls for no lengthy mention here, though slight displacements are almost as numerous as the ills that flesh is heir to. Attention might be drawn to several cases recently recorded in which inflammatory disease of the gall bladder led to displacement of the stomach. Vague gastric symptoms occurred in a patient suffering from gall-stones, and persisted until at operation adhesions were found between the gall bladder and the pylorus, dragging the latter out of place and leading to symptoms due to partial obstruction and interference with circulation. A similar relation has been observed between the gall bladder and the duodenum, producing hypertrophy of the gastric muscle, as in cases of cicatricial contraction of the plyorus or duodenum. But such cases are surgical.

Displacement due to dilatation, apart from general enteroptosis, is common. The organ sags out of place in acute dilatation dependent on pyloric obstruction, malignant or benign. One frequently sees moderate dilatation and descent, especially in young women of the upper classes whose gastric muscle becomes inefficient, apparently on account of irregular and injudicious eating and drinking, lack of exercise and fresh air, constipation, and generally bad hygiene. In some of these cases one fails to find evidence of general enteroptosis, even a movable right kidney, and one gets excellent results from instituting light and dry diet, open-air exercise, regular meals and rest, with strychnine. The condition and the physical signs, however, are the same as in general enteroptosis.

Displacement due to fibrosis within the stomach itself is only too common in connection with malignant disease, in which extreme contraction and withdrawal upward are frequent. There are also cases in which a very small fibrous stomach is found after death without any ground for diagnosing cancer, and one thinks of atrophy and sclerosis following old chronic catarrhal gastritis or ulcer. These conditions are described under their respective headings.

Displacements occur in patients suffering from marked dilatation who lead their ordinary life and take their ordinary diet. That is to say, in a case of marked dilatation there is great difficulty and delay in emptying the organ and consequent undue stretching of the stomach by the weight of food and by gases, as well as by loading the organ with a meal before the previous meal has been removed. This, unless very early relieved, causes the organ to sag downward out of place. Any pyloric obstruction—which leads to dilatation, as it constantly does—may be an indirect cause of marked displacement. The most common causes of pyloric obstruction are, of course, malignant disease, cicatricial contraction following ulcer, hypertrophic stenosis, adhesion to neighboring organs, and compression from without. These are fully described elsewhere.

Gastroptosis (displacement downward of the stomach).—This nearly always is associated with enteroptosis (*q. v.*).

Direction of Displacements.—Displacement upward has been mentioned in connection with fibroid lung, tympanites, etc. Cases have been described in Germany extreme enough to cause narrowing of the cardiac orifice (Fleiner). Lateral displacement has been mentioned. In the downward displacement of enteroptosis, at first sight the entire organ seems lower. Strictly speaking, this is not the case, for the cardiac end remains a fixed point or hinge, the pylorus descending. The commonest form then is

FIG. 4551.—Subvertical Descent of the Stomach in a Nullipara, Aged Twenty-eight. (From Riegel.)

the subvertical. In this form the upper curvature, instead of lying horizontally across the abdomen with concavity upward, passes obliquely from the left of the patient downward to the right. Meinert found this surprisingly common in women. In fifty girls, aged about twelve years, fifty per cent. had this displacement, and in his gynecological clinic ninety per cent. had it, while in the males examined only five per cent. showed the condition. In a paralyzed chest, in pigeon breast, this is the form of displacement.

A common form is the loop or horn shape in which the part midway between the cardia and the pylorus sags and descends perpendicularly, while the line joining the extremities of the organ remains nearly horizontal.

In determining the nature of the dislocation it cannot be too strongly emphasized that one must consider the position of the pylorus and that of the lesser curvature. Only when these two are lower than normal can one speak of displacement downward—gastroptosis. The determination of the site of the lower border is valueless in attempting to prove a displacement downward, for a lowering of the greater curvature does not prove gastroptosis.

Normally, the pylorus is hidden under the right ribs at about the level of the ensiform process, and, as the lesser curvature begins at the pylorus, it too is invisible even

FIG. 4552.—Descent of a Loop- or Horn-shaped Stomach in a Married Woman, Aged Thirty-one. (From Riegel.)

when the stomach is inflated. This leaves the body of the stomach to round out into relief the upper epigastrium, which rounded prominence excludes marked gastroptosis.

In gastroptosis the epigastrium is flat or sunken, while below this area there is often a fulness which on further examination may be shown to be the descended stomach. This is pathognomonic of gastroptosis. In extreme cases one finds the lesser curvature at the level of the umbilicus. In an elderly multipara coming to the Outdoor Department of the Royal Victoria Hospital, with rather slight, vague, gastric symptoms, especially sense of weight, we found on inspection of the abdomen, the patient being supine, a relaxed abdominal wall, the upper epigastrium concave, and exactly at the level of the umbilicus a fulness began which moved freely with respiration—the lesser curvature. In another woman, middle-aged and nulliparous, of good color and nutrition, whose only complaint was "dyspepsie gazeuse," one heard on sharply tapping the abdomen a loud succussion, and on inflation of the stomach one saw the lesser curvature readily; the stomach was enormously dilated and the greater curvature reached to the brim of the pelvis.

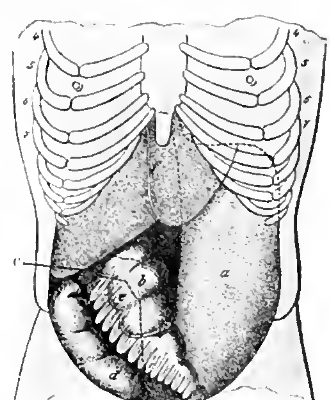

FIG. 4553. Vertical Stomach. (Kussmaul.) Extreme descent, the stomach hingeing on its cardiac orifice. The case illustrates the difficulty and delay which the organ experiences in naturally expelling its contents, and also the dilatation which is sure to result from this state of affairs. *a*, Stomach; *b*, pylorus (in dotted lines); *c*, gall bladder; *d*, caecum; *e*, transverse colon with the omentum majus rolled up; lower down, the omentum is wound around the colon.

This association of dilatation and displacement is very frequent and represents a causal relationship. R i e g e l ' s experience goes to show that dilatation plays a great rôle in the production of gastroptosis, and the dilated stomach very frequently, if not always, lies lower than normal. Sometimes it is impossible to say which is primary; for the mere overloading of the dilated stomach leads to gastroptosis, and it is also true that gastroptosis itself renders difficult and delayed the expulsion of food; hence distention and dilatation. Yet gastroptosis is frequent without dilatation, surprisingly frequent in young females without gastric symptoms or signs, and with no changes in the gastric secretion. Corsets are a common cause of this; kyphosis and scoliokyphosis have the same effect.

The more nearly vertical the stomach is, *i.e.*, the farther down the pylorus has descended, so much the more difficulty—as Kussmaul long ago pointed out and figured—has the stomach in emptying itself; and the fundus diminishes in capacity while the pyloric region increases. This leads to actual kinking in the lesser curvature and necessary retention, atony, and dilatation. Cases so extreme as that shown in Fig. 4553 are very rare. More common are the subvertical, or the loop-shaped displacements. All gradations occur, but never a descent of the entire organ, except in marked displacement downward of the entire diaphragm.

ETIOLOGY.—The very great variety of forms of displacement makes it very unlikely that one single cause accounts for all cases (as Glénard believed); and, what is more important, there are many cases of enteroptosis without any relaxation of the hepatico-colic ligament. Riegel believes that gastroptosis results from the stomach's accommodating itself to changes in the space conditions in the abdomen, by whatsoever process brought about.

DIAGNOSIS.—The condition is far oftener overlooked than recognized, mainly because we emphasize chemical tests and the position of the lower border, neglecting the motor power and the *site of the pylorus and of the lesser curvature*. Palpation and percussion alone almost never give accurately a diagnosis of gastroptosis. Percussion, after the patient has drunk water, gives information concerning the lower border, but it is not sufficient for a diagnosis of either displacement or enlargement.

There is only one method which is accurate and easy of performance, and that is inspection, with perhaps palpation and percussion, after inflation.

Electric transillumination is more complex and offers no greater accuracy.

Gastroptosis promptly affects other organs, and first, as a rule, the right kidney. In wellnigh all marked cases of gastroptosis, of any standing, one can readily feel the moving kidney, either the rounded lower extremity leaving its normal position a trifle, or nearly the entire organ which one can grasp and control, or the whole kidney which one can seize and move over a large area. A freely movable kidney does not prove the presence of a mesonephron, for this latter is very rare, while the former is fairly common.

The liver, too, comes in for displacement, in the recognition of which one must pay particular attention to the upper border as in the case of the stomach.

The colon, particularly the transverse colon, is frequently found similarly displaced, as may be demonstrated by rectal injections of air or water.

The etiology is fully discussed in the article on *Enteroptosis*, in THE APPENDIX.

SYMPTOMS.—Kussmaul believed that the nervous manifestations produced the motor insufficiency, Glénard the reverse. Most authorities now hold that gastroptosis plays an important part in causing nervous symptoms. There remains the fact that in persons having gastroptosis and other displacements, symptoms of gastric distress, as well as nervous, hysterical, or neurasthenic symptoms, are frequent, though such symptoms occur without gastroptosis, and vice versa. Gastroptosis and these symptoms belong as a rule to women only. If such nervous symptoms depended on gastroptosis we would expect to find them in the few males who suffer from gastroptosis, but Bial found that of the males with the complaint, fifty per cent. had no subjective symptoms. For this reason Riegel believes that a suitable disposition on the part of the central nervous system is essential to the production of these symptoms.

Gastroptosis itself has a train of symptoms—*e.g.*, a sense of fulness and weight after meals, an increase of the length of time required for digestion, eructations of gas a long time after meals, borborygmi, especially on the left side, and generally relieved by removing tight clothing. It not uncommonly leads to motor insufficiency, while the chemistry in the stomach is likewise sometimes disturbed. The chemical changes, however, are not always directly due to the displacement. The motor insufficiency, however, does lead to retention, fermentation, and gas, all of which rarely irritates the mucous membrane and affects the secretion. Much oftener the altered secretion is a complication. This gastroptosis is accompanied sometimes by increased, sometimes by diminished secretion. So chlorosis often has with it hyperchlorhydria. But hyperchlorhydria and gastroptosis, though associated, are independent, and both or either may accompany chlorosis.

TREATMENT.—The treatment of this displacement is multiform. Those examples which are due to the wearing of constricting clothing are preventable. After parturition a great deal can be done by aiding the abdominal muscles, combating tympanites, opening the bowels regularly, keeping the patient supine till the abdominal muscles are fit to do their work. The treatment of the gastroptosis itself, as of nephroptosis, is largely mechanical, and a well-fitting belt or properly adjusted corset gives great comfort and distinct assistance. Some mild cases are cured by the horizontal position assumed in the treatment of some other complaint. The German "fat cures" do increase the fat, but aid more probably by the horizontal position being more frequently chosen. In acute cases, lying down with the clothes loosened may be definitely prescribed.

The diet is all-important and should be light and dry, given in small amounts, easily digested and nourishing; for example, eggs, milk, cocoa, junket, toast, meat in small quantity, and greatly restricted carbohydrates; but it should always be adapted to the gastric juice in the individual case, as made out by chemical examination.

Surgeons have obtained good results by folding and stitching the enlarged and displaced stomach, reefing it in as it were, but results are not as yet satisfactory enough to warrant operative procedure in all cases that give symptoms.

Charles F. Martin.
F. Morley Fry.

STOMACH, THE SHAPE, POSITION, AND MOVEMENTS OF.—The best method of studying the form and size of the stomach is to remove the organ as soon after death as possible, to inflate it with air, then to tie off both extremities and permit it to dry. By this method the stomach is usually slightly overdistended, and attains a size not quite reached during life. The usual form of the stomach is represented by Fig. 4554, and cannot easily be described by a phrase. The part to the left of the œsophageal orifice is called the fundus; that part which lies nearest the pylorus is called the antrum pylori. The right half of the stomach is called the pyloric half; that to the left the cardiac half. The stomach is exceedingly variable in shape. When empty it contracts, and after a prolonged fast of many hours it may be almost cylindrical in shape. This cylindrical appearance is most marked in the pyloric half, so that this portion of the stomach may markedly resemble the transverse colon in contour. The same condition of the pyloric half may be found at the autopsy if death has occurred during the height of digestion. It is not uncommon, under such circumstances, to find a constriction near the middle of the stomach, separating in a greater or less degree the cardiac from the pyloric half.

The measurement of about two hundred adult stomachs gives the following average dimensions: Length, 25.5 cm.; vertical diameter, 12.5 cm.; antero-posterior diameter, 11.9 cm.

The length is a trifle more than twice the height, or as 100 to 49; the height is to the antero-posterior diameter as 100 to 95. Berry and Crawford state that the antero-posterior never exceeds the vertical diameter. I have found the antero-posterior diameter longer not infrequently, especially in very young children, and it may be that as the children grow older the vertical diameter develops more rapidly than the antero-posterior one.

The vertical diameter is subject to very marked variations; it may be so great as almost to equal the long diameter, or, on the other hand, it may be very short. The fundus also varies greatly. Nearly one-half of the stomach may lie to the left of the cardiac orifice; or the fundus may be altogether wanting. As an average the part to the left of the œsophagus is a little more than one-fourth of the total length of the stomach. This proportion holds true for all ages, from early fœtal life to old age. I have examined many fœtal and infantile stomachs, and cannot detect any peculiarities of outline belonging to any particular age. The fundus is developed very early in fœtal life, often as early as the third month of utero-gestation; and fœtal stomachs present as many variations of shape as do adult stomachs. If an inflated stomach is examined on its upper surface it will be noticed that the œsophagus does not enter the stomach at a point equidistant from its anterior and posterior surfaces. The cardiac orifice is invariably much nearer the anterior than the posterior wall of the stomach (see Fig. 4555). This asymmetry of insertion is constantly present, occurring in all the stomachs, both fœtal and adult, which I have examined; but it varies considerably in degree. In general it may be stated that about two-thirds of the antero-posterior diameter lies behind the cardiac orifice, and one-third in front. Rarely is the orifice very near the centre of the antero-posterior diameter; never at the centre or behind it.

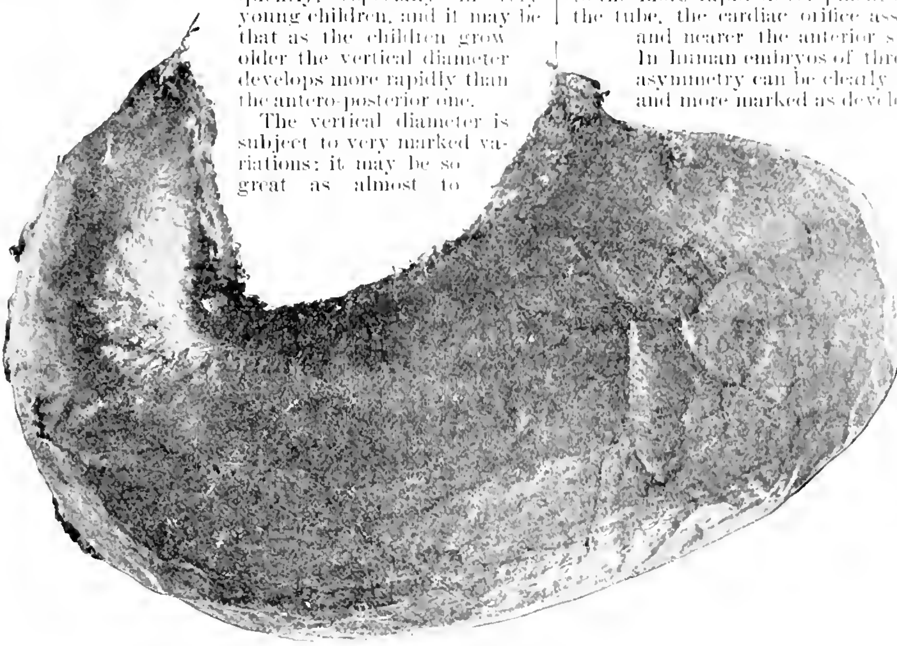

FIG. 4554.—Normal Adult Stomach.

An explanation of this anatomical peculiarity may be found by attention to the development of the stomach. Originally the stomach is a simple tubular prolongation of the œsophagus. In human embryos of the sixth week the form is no longer cylindrical. The posterior surface of the tube (that directed to the spinal column) bulges considerably (greater curvature); the anterior surface is slightly depressed (lesser curvature). During the third month the stomach undergoes decided change in position. In the first place it twists on its sagittal axis in such a manner that the long axis of the stomach instead of lying parallel with the spinal column thereafter lies obliquely, the fundus thereby moving to the left of the median line, the pylorus to the right.

In the second place, a twist occurs in the long axis of the stomach and lower part of the œsophagus in such a way that what was the left side becomes the anterior one; what was toward the right turns backward. Owing to the more rapid development of the posterior part of the tube, the cardiac orifice assumes a position nearer and nearer the anterior surface of the stomach. In human embryos of three and four months this asymmetry can be clearly seen, and becomes more and more marked as development progresses.

Position.—A simple way to study the position of the stomach is to make an œsophagotomy as soon after death as possible, to introduce a rubber tube through the orifice into the stomach, and then to fill the organ with water. When this method is employed the cardiac orifice is always found on the left side of the body in front of the tenth dorsal vertebra. It is there held firmly in position. The greater curvature ascending from this point rises as a rule to the upper border of the sixth rib in the anterior axillary line, sometimes so high as the fifth rib, causing the fundus to lie behind the heart. The greater curvature then sweeps around, descends vertically a short distance, then turns in its descent to the right, passing the free border of the ribs on about the level of the junction of the ninth and tenth ribs, runs from one to three inches above the umbilicus, and finally turns up and to the right to reach the pylorus.

The pylorus in the male lies as a rule on the body of the first lumbar vertebra, 4–6 cm. to the right of the median line. It is always more or less movable, usually not more than 2 cm. in any direction. The pylorus lies 6–8 cm. lower than the cardia, and about the same distance to the right of it. It is evident that the lesser curvature, which is the shortest line of the stomach connecting the cardia with the pylorus, must run, taking its course as a whole, downward and to the right. It would seem easy to describe the main axis of the stomach from these data, but matters are confused by the different degrees of distention in which the stomach is seen. I have called attention above to the contracted appearance of the stomach after a several days' fast. In these cases the long axis of the stomach runs directly from above and to the left, downward to the right, and the position of the stomach is unequivocally oblique.

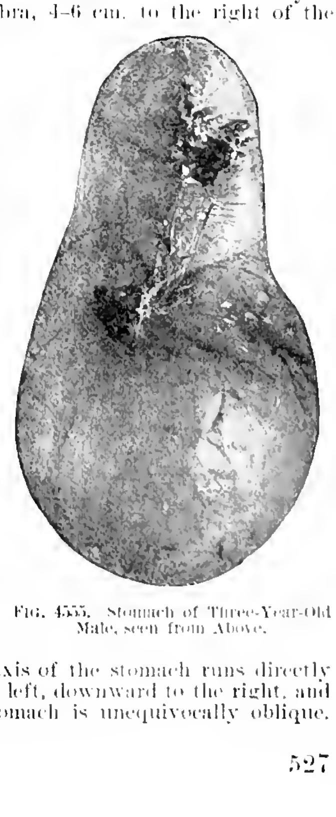

FIG. 4555.—Stomach of Three-Year-Old Male, seen from Above.

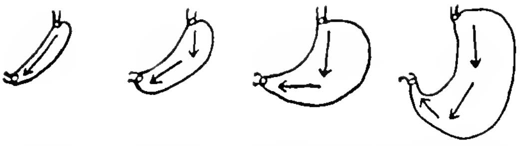
When the stomach fills it sinks slightly in the abdominal cavity, the greater curvature is rounded out, the lesser curvature becomes more acutely curved, and the long axis seems divided into two parts, the first part almost vertical, the second running obliquely downward to the right, and sometimes horizontal. If the stomach is fully distended the axis of the pyloric half runs upward and to the right, the axis of the cardiac half running at first vertical, then downward to the right. I have attempted to illustrate this change in the long axis of the stomach as the latter fills with fluid, by means of diagrammatic drawings made from life. Any one can verify the



1. 2. 3. 4.

FIG. 4556.—1, Contracted stomach; axis obliquely down and to the right; 2, stomach containing water; axis vertical, then oblique; 3, full stomach; axis vertical, then horizontal; 4, distended stomach; axis vertical, descending obliquely, ascending obliquely.

truth of this conception of the axis of the stomach by introducing a tube through the œsophagus into the stomach on the post-mortem table, and then watching the stomach fill with water. The most striking change is the increasing acuteness of the lesser curvature; the upper part of the stomach becomes at first doubtfully, then positively vertical; the axis of the pyloric half changes from obliquely descending to horizontal and finally to obliquely ascending (see Fig. 4556).

It is usually stated that the stomach in infants has a more vertical position than in adults. This is in the main true, but the bald statement is likely to give rise to misunderstanding. In a small proportion of infants the pylorus lies in the median line, or at least nearer the median line than in adults; but in the great majority of instances there is no decided difference. In young infants, however, the pyloric part of the stomach is relatively shorter than later in life, and it runs usually a straight course horizontally from left to right. As a result of the shortness of this horizontal part, the main portion of the stomach lies entirely to the left of the middle line, and appears therefore to be vertical. It is generally estimated that from three-fourths (Boas) to five-sixths (Hemmeter, Vierordt) of the adult stomach lies to the left of the middle line. In infants this proportion is considerably greater; in some instances so much as nine-tenths.

Movements.—The first great contribution to our knowledge of the movements of the stomach was made by Sir E. Home. He studied the stomachs of man and other mammals, and also experimented on dogs. His favorite method was to remove the stomach as soon after death as possible, turn it inside out, and thus gain an insight into the ante-mortem appearance of the stomach and of its mucous membrane. The following literal quotations from his writings will show how nearly his conclusions agree with those of later investigators. He says: "The true carnivorous stomach, as well as the human, which in its structure is closely allied to it, I found capable of dividing its cavity into two distinct portions by a transverse contraction of its coats, in which state the cardiac portion is, in length, two-thirds of the whole, but in capacity much greater." Later he writes: "I found also that the dog's stomach while digestion is going on was divided by a muscular contraction into two portions; that next the cardia the largest, and usually containing a quantity of liquid in which there was some solid food, but the other which extended to the pylorus being filled entirely with half-digested food of a uniform consistence."

"From these experiments the following facts are ascertained: That while the process of digestion is going on in the cavity of the stomach, it is divided by means of a muscular contraction of its coats into two portions; that the first receives the solids and fluids taken in by the mouth. The food is there mixed up with the secretion of the gastric glands and mucus, becomes coagulated, and by that means separated from the liquids contained in the cavity; these superfluous liquids are carried off without passing into the pyloric portion, which only receives the solid food with the necessary proportion of liquid, and in that portion of the stomach the change into chyle takes place."

Nineteen years after the appearance of Home's lectures Beaumont's classical exposition of gastric digestion was published. Beaumont was acquainted with the observations of Home. Seven pages of his treatise are devoted to the motions of the stomach. In his studies of the stomach of Alexis St. Martin he also clearly saw that the splenic and pyloric halves of the stomach had very different functions, and with great minuteness he described the mechanical processes in each part as he saw them. According to Beaumont there are two kinds of movement in the splenic half of the stomach, one causing the food to travel along a definite path, the other triturating or grinding the food and causing it to be intimately mixed. The food on entering the stomach turns to the left from the cardiac orifice, passes into the splenic extremity, follows the greater curvature to the pyloric end, and then returns along the lesser curvature to repeat the revolution again and again. Each revolution requires from one to three minutes and is produced by the circular muscles of the stomach. While these movements of the food are in progress trituration of the food is caused by a grinding motion of the stomach walls, leading to a perfect mixture of the food already in the stomach and the newly swallowed food. All of these movements are slow at first, but become more rapid as digestion progresses; the contractile force is increased in every direction, and the contained fluids are thereby given an impulse toward the pylorus. This is accomplished by the longitudinal fibres of the central and splenic parts of the stomach, aided by the circular fibres.

It is probable that, from the very moment food is received into the stomach, portions of chyme are constantly passing into the duodenum, slowly at first, more rapidly as digestion progresses. The pyloric end of the stomach can be shut off from the rest of the organ by the peculiar action of the transverse muscle, or rather of the *transverse band* (previously described, according to Beaumont, by Spallanzani, Haller, Cooper, Sir E. Home, and others). During digestion this band of circular muscle fibres alternately contracts and relaxes (at irregular intervals of from two to four or five minutes), temporarily dividing the cavity of the stomach into two parts, a cardiac half in which the food is being gently agitated and mixed, and a pyloric half which firmly presses upon the food, forcing it toward the pylorus. The action of the pyloric end can best be described in Beaumont's own words: "The longitudinal muscles of the whole stomach with the assistance of the transverse ones of the splenic and central portions carry the contents into the pyloric extremity. The circular or transverse muscles contract progressively from left to right. When the impulse arrives at the transverse band this is excited to a more forcible contraction, and, closing upon the alimentary matter and fluids contained in the pyloric end, prevents their regurgitation. The muscles of the pyloric end now contracting upon the contents detained there separate and expel some portion of the chyme. It appears that the crude food excites the contractile power of the pylorus so as to prevent its passage into the duodenum, while the thinner chymified portion is pressed through the valve into the intestine. After the contractile impulse is carried to the pyloric extremity the circular band and all the transverse muscles become relaxed and a contraction commences in a reverse direction from right to left, and carries the contents again to the splenic extremity to undergo similar revolutions."

Very little has our knowledge of the movements of the stomach advanced since Beaumont's observations were published. During the past fifteen years numerous experiments have been made on dogs without bringing many facts to light. Examination with the *x*-ray has been an exceedingly valuable means of extending our knowledge, and Cannon's contribution has been the most notable one since Beaumont's on the subject of the movements of the stomach.

The more important of the observations on dogs are here briefly reviewed: Hofmeister and Schütz removed the stomachs from freshly killed dogs and noted two kinds of contraction: (1) Very slight peristaltic waves traversing the cardiac half and most pronounced at the beginning of the antrum pylori; (2) vigorous contractions of the pyloric half which becomes entirely shut off at the antrum pylori from the cardiac half. These contractions narrow and shorten the pyloric end and press the food against the pylorus, which closes tightly. Only when solid particles are pressed against the pylorus is there any real antiperistaltic wave in the sense of Beaumont (*vide supra*).

Rossbach observed on dogs that, during digestion, no peristaltic waves of any kind occur in the fundal portion of the stomach, which simply remains passively contracted upon its contents. Peristaltic movements always begin at about the middle of the stomach and take twenty seconds to extend from there to the pylorus. This contraction of the pyloric half is so violent that it completely obliterates the lumen of that portion of the stomach. Rossbach noted that the pylorus remains closed during the whole process of digestion (from four to eight hours), and then the food is propelled into the duodenum in little jets.

Von Mering also states that the stomach of the dog empties itself rhythmically, contractions occurring every twenty seconds.

Moritz made duodenal fistulæ in dogs. He observed that water begins to be forced into the duodenum almost immediately after its ingestion, and that all the water leaves the stomach at latest twenty to thirty minutes after it is swallowed, being squirted into the duodenum rhythmically. Moritz, by manometric observations in the human stomach, showed that no peristaltic contractions occur in the cardiac half, but that rhythmic waves occur in the pyloric extremity.

Roux and Balthazard by means of the *x*-ray studied the movements of the stomach in dogs and men. They noted that the stomach during digestion is divided into a splenic and a pyloric part; that peristaltic contractions occur almost immediately after food is swallowed; that peristaltic waves pass over the stomach in man from left to right, traversing the stomach in twenty seconds, and recurring with great regularity every fifteen to twenty seconds.

Cannon has published the most extensive and valuable observations with the *x*-ray. He experimented on cats. The cats were starved for twelve hours, and were then fed on dry bread made pulpy with milk or gravy or hot water, and mixed with varying proportions of bismuth subnitrate. Within five minutes after food is taken a few constriction waves pass over the extreme pyloric end of the stomach. Two to three minutes later the stomach begins to be constricted near the middle, and slight peristaltic waves originate there and pass to the pylorus. As digestion proceeds the antrum pylori elongates, the depressions grow deeper, the peristaltic waves recurring with almost clock-like precision every ten seconds, and requiring thirty-six seconds to travel from the middle of the stomach to the pylorus. During digestion the cardiac half of the stomach acts as an active reservoir; the walls contract as the food gradually passes on into the pyloric half. There are no currents of food in the fundus. The part of the stomach which narrows its calibre first is the middle of the stomach, the so-called preantral portion. To the left the contractions of the fundus force the food very sluggishly onward into the preantrum, which in turn contracts much more vigorously, squeezing the food into the antrum pylori. In the antrum the food is thoroughly triturated and mixed with the gastric secretions, and expelled thence into the duodenum with considerable power. Ten to fifteen minutes after peristalsis begins food enters the duodenum. It is often squirted with force 2–3 cm. beyond the pylorus. Not every constriction wave forces food into the duodenum, except toward the end of digestion. One hour after food was given Cannon noted that three waves in succession forced food through the pylorus; then no food passed during eight subsequent waves; the next wave again forced food through; the next two did not; the next four waves again expelled food; then followed three ineffectual waves, and thus the food was squirted into the duodenum at rather irregular intervals.

The pylorus usually though not always stops solid particles, and often these are shot back with considerable rapidity several centimetres along the antrum. Occasionally solid pellets enter the duodenum. There is no true antiperistalsis. The food in its path from fundus to pylorus is not moved progressively forward. It follows a zigzag course forward and backward, requiring in the cat nine to twelve minutes to reach the pylorus after having reached the zone where the peristaltic waves affect it.

During vomiting the pyloric antrum contracts violently, expelling its contents into the relaxed fundal half, from where it is forced by contraction of the abdominal muscles into the œsophagus.

STOOLS. See *Fæces*.

STORAX (*Styrax*, U. S. P., P. G.; *Styrax Præparatus*, B. P.; *Styrax liquide*, Cod. Med.) is a balsam prepared from the inner bark of *Liquidamber orientalis* Miller (fam. *Hamamelidaceæ*). This balsam is a disease product, resulting from wounds inflicted upon the bark of the medium-sized tree named above, which resembles the sweet-gum tree (*L. Styraciflua* L.) of the Eastern United States.

The styrax tree occupies a limited area in the southwestern districts of Asia Minor, where it forms forests. It is collected by bruising, and after some time removing the outer bark, then scraping off and boiling the inner bark with sea water. The oleoresin thus melted out rises to the top and is skimmed off. By pressure, an additional amount can be obtained from the remaining bark.

Storax is a semi-liquid, gray, sticky, opaque mass, depositing, on standing, a heavier dark-brown stratum; transparent in thin layers, and having an agreeable odor and a balsamic taste. Insoluble in water, but completely soluble (with the exception of accidental impurities) in an equal weight of warm alcohol. If the alcoholic solution, which has an acid reaction, is cooled, filtered, and evaporated, it should leave not less than seventy per cent. of the original weight of the balsam, in the form of a brown, semi-liquid residue, almost completely soluble in ether and in carbon disulphide, but insoluble in benzin. When heated on a water-bath, storax becomes more fluid, and if it be then agitated with warm benzin, the supernatant liquid, on being decanted and allowed to cool, will be colorless, and will deposit white crystals of cinnamic acid and cinnamic ethers. This balsam consists principally of an amorphous substance named *storesin*. It also contains several *cinnamic ethers* and *cinnamate of cinnamyl* (styracin), which can be prepared in rectangular prisms, and *cinnamic acid* and *styrol*.

Storax goes principally to the East, very little being used in European pharmacy; in its action it varies very little from a number of other balsamic substances; internally it has been used in bronchitis and similar conditions with but moderate success. As an ingredient of liniments, ointments, etc., it is quite useful. The compound tincture of benzoin contains eight per cent. of storax. Dose of storax, from three to five drops.

ALLIED PLANTS.—The Sweet Gum Tree, *Liquidamber Styraciflua* L., resembles the above species and supplies a non-drying sticky balsam resembling storax in medicinal properties, although not in color or opacity.

Henry H. Rusby.

STORM LAKE MINERAL SPRING.—Buena Vista County, Iowa.

POST-OFFICE.—Storm Lake. Good hotel accommodations.

This spring is located one mile from the village of Storm Lake, at an elevation of 900 feet above the Mississippi River. The surrounding country is level, and not especially interesting. The temperature ranges from about 70° F. in summer (average) to zero in winter. The following analysis is by Walter L. Brown, analytical chemist, of Chicago: One United States gallon contains (solids): Sodium chloride, gr. 0.18; potassium sulphate, gr. 3.02; sodium sulphate gr. 3.22; calcium sulphate, gr. 35.12; magnesium sulphate, gr. 3.40; magnesium bicarbonate, gr. 10.78; silica, gr. 3.56; iron oxide and alumina, gr. 0.18; organic matter, a trace. Total, 59.46 grains. There is also present a large amount of free carbonic-acid gas. The water is said to be efficacious in diseases of the liver, bowels, and kidneys.

James K. Crook.

STRABISMUS, or **SQUINT,** is that condition in which the visual axes are not both directed toward the point looked at. It causes diplopia, and the eyes may be seen to be turned in different directions.

Diplopia arising from strabismus is binocular, and is noticed only when light from the object looked at forms a sensible image on each retina; and when the visual centres are so related to each other as to possess the power of binocular fusion.

Normally, when a certain point is looked at, its image in each eye falls on the fovea; and the two produce the idea of a single point. When, however, the point looked at makes its impression on the fovea in one eye, but on

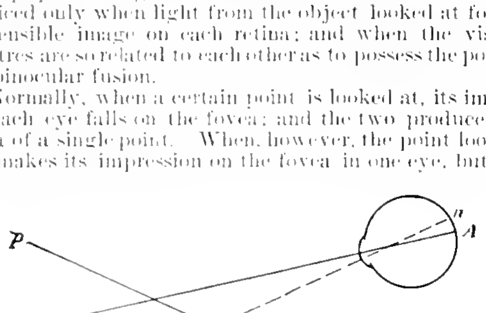

FIG. 4557.

some other portion of the retina in the other, it generates the idea of two distinct points some distance apart, the impression on the fovea being referred to a point directly in front of the eyes, while the impression on another part of the retina is referred in a different direction. Thus, in Fig. 4557, representing a case of convergent strabismus, the visual axis of the eye *A* being directed to the object *O*, the visual axis of the eye *B* is directed elsewhere, to *P*.

In the eye *A* the impression of the point *O* will be made at the fovea; but in the eye *B* the light from *O*, entering in the direction of the broken line *O m*, will make its im-

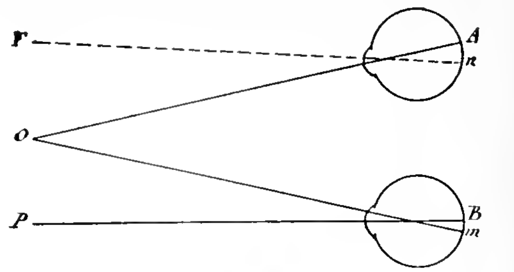

FIG. 4558.

pression on the point *m*, some distance from the fovea. Since the impression is made on *A* at the fovea, it will be correctly referred to the object looked at. But in *B* the impression made at *m* will be referred to a point to one side of the object looked at; its position relative to *O* being in the direction *n F*, which makes the same angle with the visual axis of *A* as *O m* makes with the visual axis of *B*. The image of the point received on *A*, and referred to its true position *O*, is called the *true image*. The image received at *m*, and referred to *F*, in the direction *n F*, is called the *false image*.

In Fig. 4558, representing what occurs in divergent squint, the eye *A*, turned toward the object *O*, receives on its fovea the true image, which is referred to its proper source; and the eye *B* receives at *m* the false image, which, with reference to the true image, is referred in the direction *n F* to *F*.

In general, *in whichever direction the squinting eye deviates, its false image appears to be situated to the opposite side of the true one.* When the image on the right belongs to the right eye, it is called *homonymous diplopia*. It occurs when the visual axes are crossed as in Fig. 4557. When the image on the right belongs to the left eye and the image seen to the left belongs to the right eye, it is *crossed diplopia*. This is represented in Fig. 4558, and occurs in divergent squint. To determine which image belongs to the right eye, and which to the left, cover one eye and the image belonging to it will instantly disappear. Or place before one eye a piece of colored glass, when the image belonging to that eye will appear colored.

Objective Symptoms.—If the squint be well marked, inspection will reveal the defect, and show which eye deviates. But there is a possibility of error. We judge of the direction of the visual axis by the direction of the cornea. Usually the visual axis pierces the cornea near its centre. But sometimes the visual axis deviates, so that, when properly directed, the centre of the cornea will be turned considerably to one side, and the eye will appear to squint.

To determine whether the eye really does squint, direct the patient to gaze steadily at a certain object, and cover first one eye and then the other. If both eyes are properly directed, there will be no change of position when either one is covered. If one eye have its visual axis turned elsewhere, covering it will not cause any change of position; but covering the eye which has been directed toward the object will cause the eyes or head to be turned, so that the eye which had looked elsewhere may now fix on the object. If, however, both eyes have been fixed on the object, but only by an undue effort, the covered eye will deviate and take such position as can be preserved without the undue effort. The test should be repeated until the observer is satisfied as to the presence or absence of squint. Having ascertained that squint is actually present, the first point to be settled is whether it is *comitant* (concomitant) or *paralytic*.

COMITANT STRABISMUS is a wrong, and usually variable, co-ordination of the movements of the eyes with reference to each other, without marked limitation of these movements in any particular direction. It commonly appears in early childhood; but may exist from birth, and more rarely begins during adult life.

Convergent squint is the most common form of comitant strabismus. In it the visual axes converge to a point nearer the eye than the one looked at, as in Fig. 4557. In it the diplopia is homonymous, and on covering the eye which is fixed on the object it turns in toward the nose, while the other turns from the nose and fixes the object.

Divergent squint comes next to the convergent in frequency. In this form the visual axes do not converge enough, either meeting at some point beyond the object looked at, or remaining parallel or even divergent. The diplopia is crossed. When the fixing eye is covered it turns out, and the other eye turns toward the nose and fixes the object. When the visual axes remain always divergent, the squint is said to be *absolutely divergent*. When the visual axes can be made to converge, but not enough, as in Fig. 4558, the squint is *relatively divergent*.

Parallel squint is applied to those cases in which the visual axes remain parallel when they should converge.

Vertical squint, in which one visual axis is directed more upward or more downward than the other, is rare, except as complicating one of the other forms of comitant squint.

Constant squint is always present, the visual axes never assuming normal relations. Opposed to it is *periodic* or *intermittent squint*, which is only present part of the time.

Periodic squint is apt to be most marked when the general tone of the nervous system is low, or at times of great excitement, or when the eyes are particularly taxed. A form of convergent squint, appearing only during strong effort of the accommodation, is called *accommodative squint*. Squint due to clonic spasm is *convulsive squint*. Closely allied to convulsive is *hysterical squint*.

Monolateral or *monocular squint* is the form in which it is always the same eye that fixes on the object looked at, while the other eye always deviates. If the fixing eye be covered it will deviate, while the ordinarily deviating eye fixes; but, upon uncovering, the deviation is soon transferred back to the eye which habitually presents it. The large majority of cases of comitant strabismus are in this sense monolateral. But it must not be supposed that only the deviating eye is at fault. The squint is a faulty co-ordination of the motions of the two eyes, and one eye deviates because the fixing eye has better vision, or sees with less effort.

Alternating squint is the variety in which the deviation is sometimes presented by one eye, and sometimes by the other: either of them becoming the fixing eye when the other is covered, and continuing to fix after the other is uncovered again.

Absence of Binocular Fusion.—Most persons with squint do not experience double vision. In some cases it is quite obvious why there is no diplopia, as where corneal opacity, or a high degree of ametropia, prevents the formation of a retinal image in the deviating eye. In other cases the reason is less obvious, yet not hard to understand; as here, although the deviating eye presents no abnormal appearance, the acuteness of vision is very low. But there is still another class of cases in which, although each eye is used, it is as an independent organ. What is called the power of binocular fusion or association is lacking.

Amblyopia with Squint.—In many cases of squint there is great defect of vision in one eye without any visible cause for it. This may be due to invisible defects in the cerebral connections of the eye, in which case it may be a cause of squint. It may also be due to failure to develop visual power through disuse, *amblyopia ex anopsia*. Or there may even have been deterioration of vision, by suppression, to prevent annoyance from diplopia.

Causes of Comitant Squint.—When binocular fusion is especially difficult or impossible, or the tendency to it unusually feeble, as where the vision of one or both eyes is very imperfect, the orbital muscles never attain that normal development which enables them to keep the visual axes properly directed to the point looked at. Anything which impairs the development of the visual centres or the acuteness of vision—as hereditary anomalies, convulsions, prolonged nutritive disorders, injury of the eyeball, keratitis, or high ametropia—becomes a cause of squint. But ametropia has an especial share in the causation of squint, as was first pointed out by Donders. Normally, the exertion of the power of accommodation is accompanied by convergence of the visual axes; the full power of the accommodation cannot be exerted without strong convergence. Hence in hyperopia, where the accommodation must be exerted more strongly, there is a special tendency to excessive convergence.

In myopia the need for complete relaxation of the accommodation, even when a near object is looked at, may lead to deficient convergence of the visual axes, or divergent squint. In myopia of high degree there is also antero-posterior elongation of the globe, which is often very marked. This makes the eyeball an oval, fitting in an oval socket, in which it cannot be turned without changing the shape or direction of the socket, by actual displacement of the orbital tissue. Hence convergence of the myopic eye requires excessive effort, while myopia, restricting the range of distinct vision, requires that the convergence should be especially great. In the highest degrees of myopia, the effort at convergence is abandoned, and a divergent strabismus permitted. This is at first relative and periodic, but, if associated with deficiencies of muscular development, is very likely to become absolute and constant.

Treatment of Comitant Squint.—The preventive treatment would include all measures favoring the normal development of the general nervous and muscular systems, or calculated to improve the acuteness of vision. Both to influence the acuteness of vision, and to give the normal accommodation and range of distinct vision, *errors of refraction are to be corrected*. In convergent squint with hyperopia, the convex lenses fully correcting the latter should be worn constantly. They should be carefully determined and put on at the earliest date possible. Children of two or three years will wear accurate correcting lenses with the greatest benefit. To make the necessary measurements for lenses, and to enforce their use, it is advisable to place the eyes under the influence of a *mydriatic*, as: Atropine sulphate, gr. i.; distilled water, ℥ ij.—one drop to be placed in each eye three times a day. This should be kept up for some time after the squint has disappeared, or for some weeks, until it is clearly demonstrated that the deviation is not being favorably influenced by it.

The mydriatic acts by paralyzing the accommodation, and so preventing any attempt to use it which may bring about excess of convergence. Care must be taken that the solution used is strong enough, and is efficiently applied. If only enough of the mydriatic is instilled to somewhat weaken the accommodation, the effect will be not to prevent, but to increase the accommodative effort, and therefore the accompanying convergence.

In myopia concave lenses, correcting it, may be used to prevent divergent squint; or, if the squint is already established, to bring about convergence.

As aiding in the proper development of the muscles concerned, what are called *orthoptic exercises* are recommended. They consist usually in looking through some form of stereoscope at lines, letters, or figures, a part of each being seen by one eye, and the remainder being presented to the other eye; by an effort these are to be fused into one picture. A reading bar or a ruler may be placed vertically between the page and the eye. The ruler cuts off a part of the page for each eye, but by using both eyes all parts may be seen. The reading of each line necessitates the alternate use of both eyes. The fusion tubes of Priestley Smith may be used for children who cannot read. Orthoptic exercises are mainly of use to cultivate the faculty of binocular fusion where that exists, but is deficient in comparison with the obstacles it has to overcome.

As a palliative of comitant squint, prisms may be worn in rare instances. They are so used as to cause the rays to enter the squinting eye in the direction of its visual axis and thus avoid diplopia, while the squint remains unchanged. Or they may be used as a sort of orthoptic apparatus, to bring the rays so nearly in the direction of the visual axis of the deviating eye that, by a little additional effort, the visual axis will be brought to coincide with their direction and the squint thus lessened. In either case the strength of prismatic effect required is to be determined by trial, and secured by placing prisms of equal strength before both eyes, with the refracting angle or thin edge of the prism in the direction in which the eyes deviate.

Operative measures are intended so to change the connection of the muscles to the eyeball that the visual axes may assume approximately their proper positions. Division of the tendon of the muscle toward which the cornea is turned allows the eyeball to be turned toward the proper position by its opponent. This is called *tenotomy of the rectus*, or *strabotomy*. *Advancement of the tendon* of the muscle which has exerted too little influence on the direction of the eye allows it to acquire a new insertion closer to the cornea, and to exert a relatively greater influence in determining the direction of the visual axis. Operative procedures should only be resorted to after other means have been carefully tried and have failed to give relief.

In determining the operation to be done the amount of deviation is to be considered. This may be measured in degrees on the arc of a perimeter, by placing the deviating eye at the centre of the arc, making the visual axis of the fixing eye parallel to the axis of the instrument, and noting the number of degrees from the axis of the perimeter to the visual axis of the deviating eye. In place of the perimeter arc, the deviation may be measured on a metre stick or tape, held one metre from the eyes. It can also be measured by placing a scale along the edge of the lower lid of the squinting eye, covering the good eye so that the other may fix, and then uncovering it and watching the deviation. As a rule, the inward deviation that can be remedied by a tenotomy of the internal rectus is greater than the outward deviation that can be overcome by a tenotomy of the external rectus; and the effect of the former operation tends to increase for a certain time after its performance, while the effect of the latter rather tends to diminish.

To perform *tenotomy* of one of the recti muscles the instruments required are a pair of scissors with fine but slightly blunt points, a pair of strabismus forceps (a form of fixation forceps with narrow-toothed jaws), a strabismus hook, and a lid elevator or speculum. A drop of a four-per-cent. solution of cocaine is to be placed over the insertion of the tendon to be cut. This is repeated every two minutes for ten minutes. The lid elevator or retractor is then introduced beneath the upper lid and confided to the assistant, who may stand behind the patient, steadying the head against his own breast. The operator with the forceps seizes a fold of conjunctiva 5 mm. back from the margin of the cornea, and over the tendon to be divided. With the scissors this fold in the conjunctiva is snipped so as to make an opening which, when stretched out, will be from 5 to 8 mm. in length. The forceps then drop the conjunctiva, are introduced through the cut, and made to grasp the subconjunctival tissue. This is also divided freely with the scissors. The hook is then introduced, the point in contact with the sclerotic, and pushed under the tendon. The forceps are now removed and the hook depended upon to fix the eyeball. The points of the scissors are introduced, one beneath the tendon and close to its insertion, the other over the tendon and immediately beneath the conjunctiva. The blades being brought together, the tendon is divided and the hook can be pushed forward without hindrance to the margin of the cornea. The point of the hook is then turned and the remaining part of the tendon taken up and divided in a similar manner. When no bands remain to prevent the hook from freely slipping forward to the corneal margin, it is removed and the motility of the eye is tested. If motion is not decidedly limited in the direction of the cut tendon, the hook is to be introduced again and other bands searched for and divided. The effect of the operation can be enhanced by freely dividing the subconjunctival tissue around the tendon.

For *advancement of the tendon* of one of the recti muscles, there are required, in addition to the instruments used for tenotomy, fine needles and silk sutures, and a needle-holder. It is better to have the patient recumbent, and, after the use of cocaine, an incision is made with the scissors in the conjunctiva, parallel to the corneal margin, 5 mm. from it and 10 mm. in length. The tendon is now to be isolated and raised on the hook. A needle armed with the silk should then be passed through one margin of the tendon from without inward, some distance back from its insertion; and, having been drawn through, is to be introduced beneath the conjunctiva near the corneal margin opposite the middle of the tendon insertion, where it is to be carried for 2 or 3 mm., in the firm scleral tissue but not through it. Then the needle is carried beneath the other edge of the tendon, and brought out opposite the first point of entrance, and the loops of suture drawn aside. The tendon is then severed at its insertion, and a small piece of it may be cut off if a decided change of the direction of the eyeball is desired. The suture is then tightened and tied, bringing the tendon forward to the desired position. The eye is closed and bandaged. The stitches are allowed to remain several days, unless it is feared that too great an effect will be produced. Tenotomy of the opposing muscle is combined with advancement to produce a marked change of direction.

In a large proportion of cases, the *result* of operative interference is only an approximate correction of the deformity, which may sometimes be improved by the subsequent use of glasses, or orthoptic training. Only where good binocular fusion can be obtained may a perfect result be hoped for.

Paralytic Squint is a lagging behind of one eye when the patient attempts to look in a certain direction; it is due to loss of power in the muscle or muscles which should turn the eye in that direction.

Such palsies may arise from lesions of the muscle itself, of the centres governing its action, or of the connecting nerve tracts. Usually they have the latter origin. Early, in a case of uncomplicated paralytic squint, movements which do not depend on the muscle or muscles affected may be normal; and, so long as no demand is made on these muscles, no diplopia or inconvenience results. The squint and diplopia appear only when the eyes are turned in a certain direction. In periodic comitant squint the squint is sometimes absent, but when present it is so irrespective of the direction of the object fixed; in paralytic strabismus the squint, though sometimes absent, is always present when the eyes are turned in a certain direction, and always absent when they are turned in another. After paralysis of one of the muscles has existed for some time, its elastic tension is no longer sufficient to balance the elastic tension of its opponent. The latter turns the eye toward itself, so that it cannot assume the normal position, even when the muscles are relaxed as much as possible. When this occurs the deviation becomes more or less constant, and if some power of voluntary contraction be recovered by the paralyzed muscle, the case assumes somewhat the character of comitant strabismus. It is convenient to classify paralytic strabismus by the nervous supply of the muscles involved.

Paralysis of the abducens nerve, or *external rectus muscle*, causes a most frequent and simple form of paralytic squint. Strabismus occurs when the patient tries to look toward the side on which the affected muscle is situated. If the paralysis be complete, diplopia begins as soon as the object fixed passes the median line; if it be but partial, it may not appear until the eyes have been directed somewhat toward the affected side. Congenital paralysis of both of the abducens nerves, causing a constant convergent squint with inability to turn the eyes to either side, has been occasionally observed.

Paralysis of the Patheticus, Fourth Nerve; the Superior Oblique Muscle.—The deviation and diplopia appear mainly when the eyes are turned toward the affected side and downward. The false image is lower, and appears so inclined that its upper end is close to the upper end of the true image.

Oculomotor Paralysis.—The involvement of all the extra-ocular branches causes drooping of the lid (ptosis), and leaves the eye unable to move in any direction except outward and a little downward. On attempting to look toward the sound side, or upward or far downward, deviation and diplopia appear, and increase *pari passu* with the effort to turn the visual axes in either of these directions. The same thing occurs when any attempt is made to converge for a near object. According to the movements attempted does the squint assume more the character of a divergent or a vertical strabismus.

When the affected eye participates in the act of vision there is experienced a great uncertainty as to the position of objects, which amounts to a kind of vertigo. If the palsy has lasted more than a few days, a permanent outward deviation of the visual axis is usually established. Oculomotor palsy may involve only a part of the muscles supplied by the nerve, or may even be limited to a single one.

Recurrent attacks of oculomotor paralysis, usually attended with intense headache, may occur. The earlier attacks are followed by recovery, but later the paralysis becomes permanent.

Ophthalmoplegia externa is the term applied to a paralysis of all the muscles attached to the eyeball.

Treatment of Paralytic Squint.—The largest number of these palsies come from some syphilitic new growth, involving the sheath of the nerve or adjoining structures, or from syphilitic disease of the nerve itself. A few come from rheumatic disease in the course of the nerve trunk, and a considerable number arise from a focus of disease in cerebro-spinal or spinal sclerosis. If there is a clear history of rheumatism, or collateral evidence of the rheumatic nature of the attack, anti-rheumatic remedies should be carefully tried. But in other cases it is best to assume that the lesion is syphilitic, and to treat it with increasing doses of potassium iodide until there is improvement, or until symptoms of iodism appear.

It is scarcely practicable to pass through the affected muscles electric currents powerful enough to have much effect on them, without endangering the optic nerve and retina.

Prisms and tenotomy are not generally of any use. Where the deformity is very great, cosmetic improvement may sometimes be obtained by making an advancement of the tendon of the paralyzed muscle and the neighboring portion of the capsule of Tenon, with a tenotomy or exsection of the opponent. The immediate effect, obtained in this way, should be a deviation toward the paralyzed muscle. In cases of incomplete recovery passive motion has been used with apparent benefit. Cocaine having been applied to the eye, the insertion of the paralyzed muscle is seized with the fixation forceps and the eyeball dragged back and forth in the direction in which the muscle would act, so that the muscle is alternately stretched and relaxed to its utmost. This is continued for about two minutes, and repeated every two or three days.

HETEROPHORIA OR LATENT SQUINT.—The perfect coordination of the movements of the two eyes, called *orthophoria*, is only effected by the demand for single vision. In a large majority of persons the withdrawal of the influence of binocular fusion leaves a perceptible squint. Such squint is called latent or dynamic, or is spoken of as an *insufficiency* of the weaker of the opposed muscles, or as *heterophoria*, a tending of the visual axes toward different points. If not great, the latent deviation will cause no trouble to a person with a well-developed musculo-nervous system. But in persons of inferior development and small reserve of nerve force, even moderate degrees of insufficiency may give rise to the symptoms of eye strain, especially if the eyes are required to do large amounts of work, or to work under unfavorable conditions.

Diagnosis of Heterophoria.—On covering one eye so that it can no longer take part in binocular vision, if there is heterophoria the excluded eye will deviate. Upon uncovering the eye, it quickly assumes again the position in which its visual axis will pass through the point fixed. In this way, by repeated trials and close watching of the eyes, quite low degrees of latent squint can be detected. The Maddox rod test is still more delicate. A glass rod held before one eye causes a distant point of light to appear as a streak. If this streak seems to go directly across the light as seen by the other eye, orthophoria is present. If the streak does not cross the light, heterophoria is present, and the direction in which the streak is displaced tells the variety of heterophoria.

To test the muscle balance at a near point a dot or figure, like that shown in Fig. 4559, is viewed through

1. 2. 3.

FIG. 4559.

a 10° prism with its base up, causing a vertical diplopia. If the balance be perfect, the false image will be exactly below the true one, as in 1, otherwise the false image will be displaced to the right or left. With the prism before the right eye, 2 will indicate esophoria, and 3, exophoria.

Varieties of Heterophoria.—*Exophoria*, or insufficiency of the interni, occurs with high myopia, and from excessive near work, or as an inherent deficiency of convergence power. *Esophoria*, excessive tendency to convergence, is more often seen in hyperopes, but not exclusively. *Hyperphoria*, or vertical insufficiency, generally goes with one of the other varieties. It is right or left, according to the eye which tends to turn higher than its fellow.

Either of the above may cause headache, a "drawn feeling about the eyes," or other symptoms of eye strain. But such symptoms should not be ascribed to this cause until errors of refraction have been accurately corrected.

Treatment.—All remedial measures for squint may be resorted to. On account of the lesser extent of the deviation, prisms are particularly available. On the same account tenotomy and advancement require more accurate and delicate adjustment to the needs of the case, and are to be resorted to only after a thorough and prolonged acquaintance with those needs. Reduction of the amount of trying eyework, and hygienic measures calculated to improve the condition of the nervous system generally, are of the utmost importance in such cases.

Mixed Forms of Squint.—While nearly all cases of strabismus are readily referred to one or the other of the foregoing classes, and while it is of the first importance to have clear conceptions as to the special characteristics of each class, it should not be forgotten that many cases present the peculiar features of more than one class. In strabismus, therefore, each case is a subject for individual study. *Edward Jackson.*

STRAMONIUM LEAVES AND SEED.—(*Stramonii Folia*, U. S., Br.; *Folia Stramonii*, P. G.; *Stramonii Semen*, U. S. P.; *Stramonii Semina*, Br.; *Stramoine* or

FIG. 4560.—Flowering Branch of Datura Stramonium, with Fruit. (Baillon.)

Pomme epineuse, Cod. Med.; *Jamestown Weed*, *Thorn-apple*, *Apple of Peru*, *Stinkweed*, etc.). The two drugs are defined respectively as the dried leaves and the dried seeds of *Datura Stramonium* L. (fam. *Solanaceæ*). The stramonium plant is probably a native of Southern Asia, but it has become abundantly naturalized in nearly all subtropical and temperate regions. It is very common in rich soil of waste places in the Eastern United States. It is a coarse, smooth annual, from one to six feet high, with an upright tri- and dichotomously branched, smooth, green, more or less hollow stem, branching at, say, a foot from the ground, and forming a spreading crown. The habit of the flowering and fruiting branches, and the structure of the large, white, fragrant flowers, and of the fruit, are shown in the accompanying illustrations.

DESCRIPTION.—*The Leaves.*—A much-wrinkled, deep or somewhat grayish-green, rarely very slightly brownish mass, consisting of petioled leaves, the blades from 12 to 25 cm. (5–10 in.) long, and about two thirds as broad, inequilaterally ovate, very oblique at the base, acuminate and

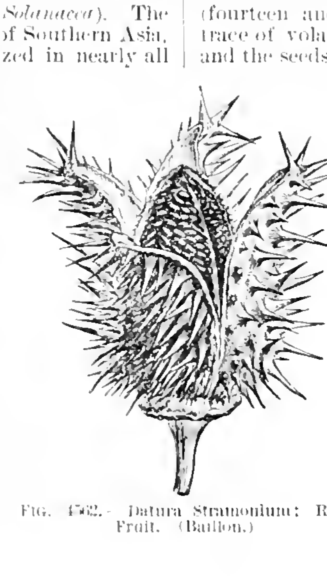

FIG. 4562.—Datura Stramonium: Ripe Fruit. (Baillon.)

acute at the apex, very coarsely dentate or sublobed, the large teeth few, acute, with rounded sinuses, thin, smooth; the principal veins few and coarse; odor slight, narcotic when bruised; taste bitter and disagreeable.

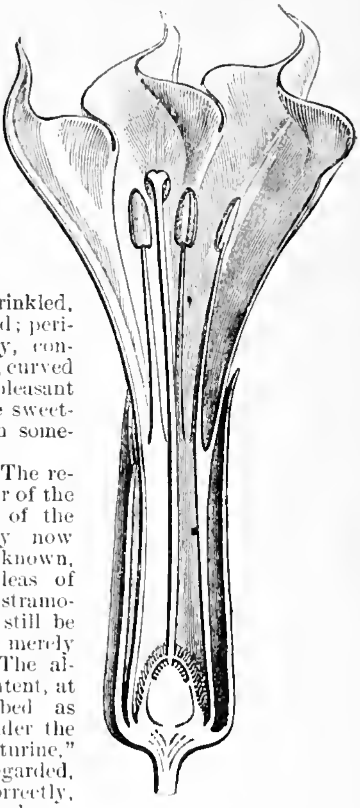

FIG. 4561.—Longitudinal Section of Flower of Datura Stramonium. (Baillon.)

The Seeds.—About 3.5 mm. ($\frac{1}{7}$ in.) long and two-thirds as broad, flattened reniform, the hilum at one side of the concavity; testa dull black or blackish, hard, coarsely and shallowly reticulate-wrinkled, and very finely pitted; perisperm whitish, oily, concealing a cylindrical, curved embryo; odor unpleasant when bruised; taste sweetish and bitter, then somewhat acrid.

CONSTITUENTS.—The relations to one another of the mydriatic alkaloids of the *Solanaceæ* are only now becoming known, and our ideas of those of stramonium must still be regarded as merely tentative. The alkaloidal content, at first described as distinct, under the name "Daturine," is now regarded, doubtless correctly, as being largely one of the *hyoscyamines* (see *Scopola*), but which one, and in what proportions, and how far, and under what conditions mixed with atropine, are matters largely of conjecture. Even the percentage of total alkaloid is not well known. It is generally considered that the seeds contain about one-fourth of one per cent., the leaves not more than one-third as much. Besides these, the leaves contain a large amount of ash (fourteen and one-half per cent.), nitre, asparagin, a trace of volatile oil, and other unimportant substances, and the seeds about twenty-five per cent. of fixed oil.

ACTION AND USE.—From the above analysis it will be seen that stramonium can exhibit but little difference in action from hyoscyamus, and but little from belladonna. It is indeed capable of being used for exactly the same purposes, only it is more quieting and hypnotic than the latter, which may indicate the presence in it of some hyoscine or other alkaloid distinct from atropine or hyoscyamine. Custom, perhaps, as much as anything, has directed the leaves of this species, instead of those of the others named, to be used in the local antispasmodic treatment of asthma, for which purpose it is almost entirely prescribed. The common method is to administer it by smoking. The leaves may be burnt in a pipe or on the cover of a hot stove, or they may be made more inflammable by being soaked in a strong solution of saltpetre and dried, after which they will burn steadily, without flame and without requiring any apparatus; prepared in this way and flavored with aromatics and balsams, they are the foundation of most of the "asthma cigarettes" and "pastils," which are often better products than extemporaneous preparations are apt to be. The French Codex gives directions for making cigarettes of stramonium, containing 1 gm. each of leaves, without any admixture. For internal administration stramonium may be considered as about the equivalent of hyoscyamus. The following preparations are official, all made from the seed, the leaves being only used for smoking (1 or 2 gm.): Extract (*Extractum Stramonii*), strength about $\frac{4}{1}$: Fluid Extract (*Extractum Stramonii Fluidum*), strength, $\frac{1}{1}$; Tincture (*Tinctura Stramonii*), strength $\frac{1}{15}$; and the Ointment (*Unguentum Stramonii*), strength (of the extract), $\frac{1}{10}$ in benzoinated lard. All these have similar properties and uses to the corresponding preparations of hyoscyamus and belladonna, but are more hypnotic than the latter. Dose of fluid extract about 0.2 c.c.; of the other preparations, according to their relative strength.

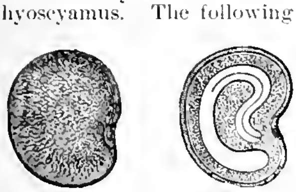

FIG. 4563.—Seed, Entire and in Section, of Datura Stramonium.

ALLIED PLANTS.—*Datura*, of which the present plant is a characteristic species, consists of a dozen, mostly large, rank herbs, most of which have similar medical properties to the above. *D. Tatula*, with purple stems and flowers, scarcely distinct from *D. Stramonium*, and *D. alba*, of India, are used for the same purposes.

Henry H. Rusby.

STRANGULATION AND HANGING, EVIDENCES OF DEATH FROM.—Suffocation is the name applied to both the act and the result of deprivation of atmospheric air. When this deprivation is due to mechanical interference the term *mechanical suffocation* is used.

Mechanical interference may occur through pressure on or obstruction within some portion of the respiratory tract. Suffocation by pressure on the neck is called *hanging* when the constricting force is the weight of the body itself, and *strangulation* in all other cases. The term suffocation is also used in a more special sense where breathing is prevented by pressure on the mouth, nose, chest, or abdomen; or by obstruction within the respiratory tract; or by pressure on the tract from the œsophagus; or through inhaling irrespirable gases.

Strangulation may therefore be defined to include all cases of suffocation by *pressure on the neck* whether by cords or the hand, but excluding hanging. The Germans distinguish strangulation by the hand as *Erwürgung*, and by ropes, cords, etc., as *Erdrosselung*. The words garroting and throttling are often used in place of strangulation. In this article the word ligature will be used to include the very varied forms of constricting materials. Hard substances are sometimes placed in the ligature to increase the pressure.

Strangulation is almost always homicidal, hanging almost always suicidal, and the other forms of suffocation usually accidental, but often also homicidal. Both suicides and murderers are usually more violent than is really necessary to destroy life; murderers more so than suicides.

Death from strangulation as well as all other forms of suffocation, including hanging, is mainly by asphyxia; to some extent by coma or syncope or both. The post-mortem appearances will vary somewhat, depending on whether the deprivation of air is sudden or gradual, partial or complete, and whether there is coincident pressure on the great arteries, veins, and nerves. According to Hofmann, a pressure of 2 kgm. on the neck stops the flow of blood in the jugular veins; one of 5 kgm., in the carotid arteries; one of 15 kgm. stops the movement of air in the air passages, and one of 30 kgm. the flow of blood in the vertebrals.

The *evidences* of death from strangulation are *external* and *internal*. The principal external evidence is the mark of the cord or hand on the neck. Tidy says that nothing short of distinct external marks would justify a medical jurist in pronouncing death to be due to strangulation, while on the other hand Taylor considers the condition of the lungs (see *infra*) as characteristic. Liman does not think there are any internal appearances which can distinguish suffocation, strangulation, and hanging from each other. This statement is made the more probable in view of the fact that death in each case is generally by asphyxia.

All marks on the body should be carefully noted, the cavities of the skull, thorax, and abdomen carefully examined; the possibility of death having occurred from other causes, even in strangulation, must be considered. In all cases the cord or strangulating ligature should be carefully examined for marks of blood, for adherent hair or other substances. The precise manner in which the cord has been tied should be noted. Putrefaction may cause external marks to disappear. In some fatal cases there are either no marks at all or they are but slight; this is more likely to be the case in suicide than in homicide, and is usually due to the ligature being soft and yielding. The victim of a homicide may, however, first be stunned and afterward strangled. A person while intoxicated or in an epileptic or hysterical paroxysm may grasp his neck in gasping for air and thus leave finger marks. Marks are said to be plainer after the body has become cold and when subjects have recovered from attempts at suicide.

The mark of the ligature in strangulation usually encircles the neck more completely and is more horizontal than in hanging. These conditions may, however, be reversed, because a body may be dragged by the neck after strangulation, and there have been suicides by hanging in whom the mark of the cord was horizontal. As a rule, however, a horizontal mark with the knot on the same level as the cord, especially if below the larynx, suggests strangulation rather than hanging; and if there are several marks the probability is even greater. In compression with the fingers the marks are not in a horizontal but in an oblique line. The mark of the ligature is usually circular, well defined, and corresponds closely to the breadth of the ligature; rather depressed and usually below the larynx. As a rule this depression is not deep; the skin at the bottom of the groove is usually very pale, while the adjacent parts are red or livid. Sometimes the bottom of the groove shows ecchymoses. Neyding says that suggillations in the groove made by the ligature on the neck are rare, but are oftener found in strangulation than in hanging, because the conditions favoring their formation are oftener found in strangulation. In most cases the skin and connective tissue of the groove and of the parts in the vicinity show, microscopically, hyperæmia and hemorrhages. Liman states that when we find suggillation in the groove or its vicinity we may know that some other form of violence has been applied at the same time as that of the ligature or hand. He had not seen suggillation in the furrow either in strangulation or in hanging, except when the injured persons had lived some time. The absence of suggillation and ecchymosis was due, he thought, to pressure on the capillaries. Bremme says that there is no hemorrhage in the subcutaneous tissues of the mark of the ligature, either in strangulation or in hanging, if death occurs at once and the cord is removed soon after death; but if the cord remains for some time after death there may be hemorrhages, or if death does not occur at once, whether the ligature is removed or not. It is impossible to distinguish ante-mortem from post-mortem hemorrhage. Different constricting agents may make quite similar marks. Taylor mentions a case in which a soft silk handkerchief was used and the appearance was the same as that of a narrow cord, due to the tightness with which it was tied. Marks may be made on the neck within a limited time after death similar to those made during life. Tidy's experiments led him to fix this limit at three hours for ecchymosis and six hours for non-ecchymosed marks. Taylor, however, doubts if such marks can be made one hour after death. He says that the period cannot be positively stated, and probably varies according to the rapidity with which the body cools.

A cord may be found near a body or even around its neck, there may even be a mark around the neck. These may be attempts at deception. Marks much like those of violence may be made by tight collars and handkerchiefs remaining till the body is cold. Cases are reported of bodies having been strangled and then burnt or hung, to cover the crime; and of partial suffocation by gags followed by or coincident with strangulation. Where a hard substance like a piece of coal or stone is inserted into the ligature (usually a soft cloth) and presses against some part of the neck, there is usually a corresponding bruise. Marks of pressure by the thumb and fingers are usually on the front of the neck, and either just above or just below the larynx. In many cases these marks are only those of the finger tips with some scratches, and show definitely the probable size of the assaulting hand and whether right or left. Marks of strangulation may disappear rapidly after removal of the ligature. Assailants usually constrict the neck much more violently than is sufficient to cause death. Marks of violence on the neck are therefore greater in strangulation than in hanging. A great variety of external injuries other than those on the neck have been found in the different cases reported, where other forms of violence were also used. With few exceptions such additional injuries indicate homicide.

Since the evidences of death in hanging are so similar to those in strangulation, and since "hanging" is not considered elsewhere in this Handbook, these evidences will be pretty freely treated here.

The external appearances in *hanging* are those due to the action of the ligature on the neck and to other violence, if any has been done, and those due to asphyxia or syncope. If the suspension is very brief and the ligature soft and supple and the body instantly cut down after death, there may be no mark. Allison questions the value of the mark, contending that it is post mortem, and reports cases; he says it is present only if the drop is considerable or the suspension continues after death. Tidy says that the mark is in a measure independent of the ligature and duration of suspension and does not usually acquire its color for some hours after death; sometimes, however, it has occurred in a much shorter time. It may be slight because the ligature has been placed over the clothing. The longer a body hangs after death the plainer is the mark. It can be produced on the cadaver. Harvey says that the characteristic mark was found in 8 non-fatal cases in nearly 1,500 cases of hanging. Coutagne, in 21 necropsies on subjects hung, found 17 in which the lesions of the neck were plain.

The *direction* of the mark in hanging is usually oblique, following the line of the lower jaw upward and backward behind the mastoid process; it may, however, be horizontal. If the ligature encircles the neck more than once, one mark may be circular, the other oblique. If a running noose is used, the mark may be circular and be seen all the way round the neck, looking like the mark of strangulation. Taylor states that if the noose should be in front, the mark may be circular, the jaw preventing the ligature from rising upward in front as much as it would behind. If it encircles the neck but once, its continuity is apt to be broken by the prominence of the hyoid bone, thyroid cartilage, sterno mastoid muscles, etc. In 117 out of 143 cases Tardieu found the mark between the chin and the larynx; in nearly all the remainder, over the larynx; in a very few, below the larynx; the last position was due to the protection of the neck by a handkerchief or beard, or there was some anatomical or pathological peculiarity which prevented the ligature going higher. Hofmann saw 2 cases of tumor of the neck; one in a woman where the cord was below the larynx, and the other in a man where it was over the larynx. Remer found the cord above the larynx in 38, over the larynx in 7, below in 2. Devergie found it above the larynx in 20, over it in 7, below in 1. Casper found it above the larynx in 59, over it in 9. Roth in 49 cases found the ligature above the hyoid bone in 5, between the bone and larynx in 31, over the larynx in 8, below it in 1. Hackel found the ligature, in 40 per cent. of cases, between the hyoid bone and larynx; in 60 per cent., lower down. The ligature always appears lower after the body is laid down than it was in suspension. Maschka found the furrow above the larynx 147 times in 153 cases.

The *character* of the mark in hanging will vary according to the kind of ligature used, its mode of application, the vitality of the tissues, and the period that has elapsed since death. The result is different according as the knot or loop is single or double, a running or slip knot. The mark may differ in character in one part of the neck from what it is in another. The same furrow may be soft in one part and dry in another. The width of the mark does not necessarily correspond to the diameter of the ligature. A double mark usually means that the ligature has been twice passed around the neck, although the marks may not be continuous or parallel. Tardieu states that a large single leather thong pressing on the neck only by the borders may make a double mark. The mark is usually depressed. The depth of the depression, groove, or furrow, as it is called, is greater the narrower and firmer the ligature, the longer the suspension, and the greater the weight of the body. The mark may be merely a slight depression, without color, or only a red blush if the subject is young, tissues are healthy, and suspension is brief. Roth in 49 cases found that the furrow of the ligature was brown in 40, red brown in 6, and 3 times bluish. In about two-thirds of the cases of hanging, as generally observed, the bottom of the furrow, the place of greatest pressure, is white, especially so where the knot is tied; while the edges of the furrow are usually slightly raised and red or livid. If the subject is very fat there may be only a slight depression. Harvey says that this hard, white, shining, translucent band from compression of the connective tissue is the first stage of the *parchment* or vellum skin, and is chiefly noticed in fresh bodies. The borders are swollen and œdematous, called by Lacassagne *bourrelet de sillon.* The skin *below* the furrow is usually violet. Authors differ as to whether this is due to congestion or to hemorrhage. Roth in 49 cases found swelling below the furrow 27 times. Hackel found ecchymoses above the mark in 35 per cent. of the cases of hanging. Hofmann thinks that the lividity of the upper border of the furrow is due to the stopping of the venous blood descending from the head.

The dry, hard, yellowish-brown, or reddish-brown *parchment furrow* described by writers on hanging is said to be common. Ogston found it in one-third of his cases. It is found only when the body has remained suspended for several hours after death; indeed, it may be produced by applying the ligature to the cadaver; is not at all, therefore, a proof of suspension during life. Liman states that constriction by a ligature even for some time does not necessarily cause a mummified or excoriated furrow. He saw cases in which the mark was soft, flat, scarcely colored, but little interrupted, and not parchmenty. Its appearance can be prevented or delayed by examining a body soon after death or by rehanging it; and after it has appeared it will disappear on the application of some liquid. Taylor compares this parchment mark to the cutis from which the cuticle has been removed for two or three days. The parchment skin is seldom seen in strangulation, though Liman has seen it. Neyding says that it depends mainly on the amount of excoriation of the skin, and that this is greater in hanging. Tardieu explains this frequency as being due to the fact that the constriction in hanging lasts longer.

The violence used in hanging may cause ecchymoses and abrasions of the skin of the neck adjacent to the mark of the ligature. Slight abrasions and ecchymoses are sometimes found in the furrow. Ecchymoses alone do not indicate whether suspension has been before or after death; but abrasion with hemorrhage strongly suggests suspension during life. Devergie regards ecchymoses of the neck as strongly suggestive of homicide. Neyding says that suggillation in the groove is oftener found in strangulation than in hanging, and Bremme that there is no hemorrhage in the subcutaneous tissue of the mark if death occurs at once and the cord is removed at once after death; but if the cord remains for some time after death there may be hemorrhage, or if death does not occur at once, whether the ligature is removed or not. Roth found ecchymoses or small bladders at the lower margin of the furrow 9 times in 49 cases. Riechke found only once in 30 cases a hemorrhage beneath and on both sides of the mark. Chevers did not find ecchymoses of the skin of the mark in cases of hanging. Coutagne found hemorrhage into the connective tissue or muscle. Casper found no ecchymoses in 50 out of 71 cases. Maschka saw 2 cases where burns on the neck resembled the mark of a ligature.

The furrow when once distinct remains constant for a long time after death even in putrefaction. Marks from soft substances, however, disappear sooner than those from strong and uniform compression. The value of the presence or absence of marks on the neck and the character of the marks have been questioned. Orfila, Casper, and Vrolik have shown by experiment that if a body is hanged within one or two hours after death the furrow, parchment skin, lividity, and the density of the connective tissue will appear just as is seen when suspension has occurred during life; but ecchymoses and infiltration, clotted blood in the skin and connective tissue and muscles of the neck, suggest suspension during life.

The marks of topical medical applications, as plasters, sinapisms, etc., must not be confounded with marks of violence. In apoplectics with short, full necks we may find at the borders of the folds of the skin in the neck one or more red or livid depressions that bear some resemblance to the marks of a ligature; but on section there are no ecchymoses.

The neck nearly always appears stretched in hanging. According to Roth, the mobility of the head is increased by this stretching. The head also is always inclined to the side opposite to that of the knot. In suicides the head is usually bent forward on the chest.

Usually in *strangulation* there is hemorrhage into the loose connective tissue under the mark and in the subjacent muscles; in most cases isolated and circumscribed, but sometimes extending beyond the line of the mark. Hemorrhage from compression by the fingers is more marked than that from ligature. Sometimes there is only fulness of the subcutaneous veins.

In *hanging*, the connective tissue under the mark is usually white and condensed, the more so if the body has been long suspended. This dryness or condensation was found by Hackel in 52 per cent. of hangings. Deeper-seated parts are injured only when the hanging has been violently done. The muscles, especially the sterno-mastoid, are sometimes ruptured; Hofmann reports several cases. In 50 hangings Lesser saw 11 ruptures of muscle. Maschka never saw the rupture in suicides. Hackel in 67 cases failed to find the muscle ruptured. Hofmann believes that the rupture of the muscle is sometimes post mortem. Coutagne found the sterno-mastoid ruptured once in 24 cases.

The neck occasionally suffers extreme injury, and owing to the violence used (Tidy) this occurs oftener in strangulation than in hanging. Occasionally the neck is broken. The *hyoid bone* may be broken; Maschka saw it once in 18 of *Erdrosselung* and in 5 of *Erwürgung*. The bone is rarely dislocated in hanging. Orfila mentions a case of fracture. Barker usually found the bone fractured in judicial cases. Pellier reports 2 cases. Hofmann says the hyoid cornua are often fractured, especially when the ligature is between the hyoid bone and thyroid cartilage. Coutagne found fracture of the bone 8 times in 24 cases; he attributes the fracture to the pressure against the spine. Pellier speaks of fracture of the styloid process.

In *strangulation* the *carotid arteries* may suffer rupture of their inner and middle coats, especially in atheromatous subjects and when compression has been great. Friedberg states that the injury of the carotid is a proof that the strangulation occurred during life, and probably from pressure of the fingers on the neck without any regard to any disease of the artery. He reports two cases. The examiner should be careful not to injure the artery with the forceps. The vessels may contain clots. In *hanging* also the carotid arteries may be injured; usually the inner and middle coats are torn; and hemorrhage may occur into the wall of the vessel. The common carotids are those usually affected and just below the bifurcation, but the external carotid is also occasionally injured. The injury is said to be due to the stretching and squeezing of the artery, stretching being the most effective, since the rupture often occurs at a distance from the mark of the ligature. Such injury of the artery does not prove that hanging took place during life, because it has been produced on the cadaver; but hemorrhage into the wall of the vessel, or wound or rupture after death, is very improbable. Maschka says the lesion is very rare. Tardieu says it is rare and therefore unimportant. Pellier reports 4 cases of rupture of the carotid in a total of 23. Levy records the experiments of Hofmann of Vienna and Brouardel and himself of Paris, 5 in number, and concludes that compression of the carotids, if it produces obliteration, can cause rapid loss of consciousness and death; and explains why in incomplete suicide the subject is unable to help himself. Coutagne found rupture of carotids 10 times in 24 cases, and insists on the importance of the lesion.

In all forms of asphyxiation the *hands* are usually clinched, and may have articles in their grasp which under the circumstances have a medico-legal value. In hanging, the hands are often clinched so tightly that the nails are driven into the palms; this occurs more especially when the hanging has been done with violence. When the feet touch the ground, as often occurs in suicides, the hands may be stretched out. Roth found the hands and feet flexed in 14 of 49 cases. Taylor says that we may expect to find the hands clinched when constriction of the neck is sudden and violent. The legs are usually livid.

In *asphyxia* the *tongue* is often swollen, dark, protruding, and sometimes bitten. Maschka states that if the ligature lies above the hyoid bone the tongue will be drawn backward; if over or below the bone, the tip of the tongue may appear more or less between the jaws. In hanging the tongue is usually livid and swollen, especially at the base. According to Tidy, Dr. Guy looks on this as showing that suspension took place very probably during life. In about one-third of the cases the tongue is protruded and compressed between the teeth; sometimes bitten. Some observers found it protruded only as a result of putrefaction. The protrusion is not believed to depend on the position of the ligature. Hackel in 67 cases found the tongue lying forward in all cases in which the cord was between the larynx and hyoid; in 55 per cent. in front of the teeth, in 18 per cent. between the teeth; where the ligature was lower down the tongue was behind the teeth. He found by experiment that in the spasmodic expiratory effort the tongue was thrust forward; in the inspiratory movement drawn backward; and he concluded that the forward movement was the result of reflex action. Maschka found the tongue between the teeth 58 times in 149 cases. Roth in 49 cases found the tongue projecting and bitten in 22, the teeth shut in 15 others; in 15 the mouth was open; the tongue was retracted in 30.

In *asphyxia* the *face* usually shows pain and suffering, although sometimes the features are calm. In the latter case there may have been syncope. The face varies in color from violet to black, and may be swollen. Casper says that the face has the same appearance as in any other corpse. Liman found the face livid in only 1 of 14 cases of strangulation. Hofmann says that the cyanosis appears during the agony, because of the paralysis of the circulation and the gravitation of blood. The cyanosis of the face with projection of the eyes and the congestion of the conjunctivæ are due to the expiratory effort, and these signs are also seen in fat persons who do not die of strangulation. Tardieu mentions a dotted redness or minute ecchymosis of the conjunctivæ and skin of the face, neck, and chest as constant; but this cannot be considered characteristic, because it has been seen, though not so well marked, in death from other causes. It has been found in suffocation from compression of chest and belly, and also where there was respiratory interference in the prolonged efforts of tedious labor and in convulsions. Liman found it in those who were hanged; in the conjunctivæ, lips, back of mouth, and in the muscles. It is due, according to Hofmann, to increased blood pressure and consequent hemorrhages. It is of importance as tending to show that there was a stasis of blood in the head and face during life. Maschka in 234 cases of asphyxia found capillary hemorrhages of eyes and eyelids 87 times.

Dastre and Morat claim that in asphyxia the cutaneous circulation becomes much more active than in the normal state, while at the same time the vessels of the abdominal cavity are contracted.

Post-mortem stainings (hypostases) are usually darker in strangulation than in other forms of death. They appear soon, as does also putrefaction, because of the quantity and fluidity of the blood.

In *hanging* the appearance of the face varies with the duration of the suspension; at first it is pale, afterward livid; congested and swollen if the subject has been long suspended. Roth found the face pale in 43 of 49 cases. In about one-half of the cases the features are calm and placid (syncope). Maschka found the lips bluish in 98 of 153 cases. Harvey, after examining reports of nearly 1,500 hangings, says: "In the majority of instances, immediately after death, the features were placid, the face pale, the eyes not unduly prominent, the mouth closed or half open, the tongue pressed against the teeth but not protruding, the superficial veins full, but the head, neck, and trunk free from lividity. After a longer or shorter time, however, and apparently after a few hours (in India), all this is changed. Livid patches appear about the chest, back, and shoulders, the face and head become bloated and puffy, and the tongue and eyes protrude."

In *asphyxia* the *eyes* are usually staring, prominent, and congested, and the pupils dilated. Casper doubts their prominence. Budin and Coyne state that in asphyxia the dilatation of the pupil progresses to a maximum, and then convulsions occur. Ophthalmoscopic examination during the dyspnœa of asphyxia shows a lessened fulness of the retinal vessels. In hanging, the eyes are often prominent, staring, and congested, and usually the pupils are dilated. Lacassagne and Maschka look on ecchymosis of the eyelids and conjunctivæ, *piqueté scarlatin*, as important, favoring the idea of hanging or strangulation. Roth found in 49 cases that the eyelids were closed in 28, half open in 12, congested in 6, ecchymosed in 2; pupils dilated in 31, narrowed in 2. There was dilatation of pupils in 97½ per cent. of Ogston's cases; in 2 cases there was rupture of crystalline lens.

Signs of hemorrhage from the nose, eyes, and mouth may be visible in asphyxia, as also bloody froth from the mouth and nose. Chevers saw bleeding from the ears in strangulation. Taylor states that Dr. Geoghegan informed him of a case of suicidal strangulation by a ribbon; the violence was great, there was bleeding from the ear, and the drum was found ruptured; the mark on the neck, which was deep, nearly disappeared after the ligature was removed. Taylor also says that Wilde, of Dublin, saw a rupture of the drum and hemorrhage in strangulation. Pellier says that Littré mentions a case of rupture of the tympanic membrane in strangulation. Harvey says the blood was found flowing from the ear in 6 cases out of nearly 1,500 hangings, but no details were given. Hofmann saw a case in which there was bleeding from the ears. He says that this is not due, as has been supposed, to rupture of the tympanic membrane, but to hemorrhage from subcutaneous vessels.

In *asphyxia* the *veins* of the entire body are distended with very dark and very fluid blood, while the arteries, especially in the young, are mostly empty. Experiments on the lower animals have shown that the pulmonary artery and systemic veins to the finest ramifications are distended with dark blood.

The *mucous membranes* in asphyxia are generally much congested. Serum is found in the serous cavities. Tidy, comparing strangulation and hanging, concludes that because strangulation is usually homicidal and greater violence is used, therefore the external marks are more complete in strangulation and the congestion of the air passages is invariably much greater. Maschka found the pharynx cyanotic in 216 of 234 cases of asphyxia. Ecker reported a case of judicial hanging in a man, aged forty, where the soft palate was swollen and filled up the passage so that the air evidently could not enter.

The lining membrane of the *larynx* and *trachea* is always congested in asphyxia and may be livid; the tube may contain bloody froth or blood alone. Froth tinged with blood in the air passages is considered by Tardieu one of the most constant signs of strangulation. In strangulation the trachea is sometimes torn or may be folded on itself. The cartilages of the larynx, especially if calcareous, may be broken; this is more likely to affect the thyroid than the cricoid. The fracture would seem to occur only as the result of enormous force, especially in the young, in whom the cartilages are so elastic. The experiments of Keiller on cadavers led him to conclude that falls on the larynx, even from a height and with superadded force, are unlikely to fracture this organ; severe pressure or a violent blow against the larynx from before backward may cause fracture, but severe *lateral* pressure, as in ordinary throttling, is more likely than other forms of violence to fracture the alæ of the thyroid or even the cricoid cartilages and also the hyoid bone. Taylor states that Dr. Inman, of Liverpool, had informed him of a case of splitting of rings of the windpipe from pressure. Maschka, in 15 cases of choking, found 6 fractures of the larynx. Chailloux has collected 8 cases of fracture of the larynx in strangulation; they were all made by the fingers. The experiments of Cavasse seem to show that there is no great difficulty in fracturing the thyroid in strangulation.

Langreuter made some experiments on a cadaver from which enough of the posterior part had been removed to enable him to view the throat. He saw that lateral digital pressure on the larynx closed the glottis; stronger pressure made the vocal cords override each other. Similar pressure between the larynx and hyoid bone caused apposition of the aryepiglottic folds and occlusion of air passages. He experimented on 16 bodies to ascertain the effects of blows and pressure on the larynx, with the following results: In 8 cases, women, the thyroid cartilage was injured 3 times, the cricoid 4; in 8 men the thyroid 8 times, and cricoid 5. Whence he concluded that the larynx is better protected in women. In the 16 cases the hyoid was fractured 10 times.

In *hanging*, the larynx and trachea are usually deeply congested, of a red color; a violet color indicates putrefaction. Ogston reports mucus but not bloody froth 9 times in the pharynx, 6 in the trachea, and 4 in the lungs in a total of 40 cases. In 1 case there was a quantity of blood in the larynx and pharynx. Taylor thinks that pinkish froth in the trachea indicates incomplete obstruction; and Chevers that it is due to spasmodic efforts to breathe when the obstruction is nearly complete. Chevers always found clear mucus in the larynx and upper part of the trachea, each follicle being marked by a minute globule of mucus. Harvey states that this was noted a few times in his reports. The larynx may be fractured or dislocated. These lesions are very rare in suicide, more frequent in homicide and judicial hanging, and in the old in whom the cartilages are calcareous. Remer found the injury in but 1 case of 101 of suicidal hanging. Barker found the larynx lacerated in his judicial cases. Harvey says that the trachea was reported lacerated 11 times in nearly 1,500 cases; twice the laryngeal cartilages were separated from each other; in 5 these cartilages were fractured, but there was nothing to show under what conditions; hemorrhage in the vicinity of the larynx 43 times. Pellier reports 1 case, and adds that the lesion easily escapes notice because of the mobility of the cornua. Roth in 49 cases failed to find any fracture. Pellier found that the cricoid was injured oftener than the thyroid, which is the reverse of what is found in strangulation. Cavasse was unable to cause fracture of the larynx by hanging the cadaver. Chailloux collected 6 cases of fracture of the larynx in hanging; he concluded that the fracture could not be produced on the cadaver by hanging, and is therefore caused during life. Coutagne in 24 cases found fracture of the thyroid cartilage 8 times.

In *asphyxia* the *lungs* are usually much congested, resembling red hepatization, except that the blood is darker. Hemorrhages (apoplexies) into the substance of the lungs are common. Tardieu found patches of emphysema due to rupture of the air vesicles, giving the surface of the lung the appearance of a layer of white false membrane. Ogston admits that this occurs in pure strangulation, but to a less extent in mixed cases. Liman found the lung surface uneven, bosselated, the prominences being of a clearer color and due to emphysema; the lungs were in the same condition of congestion and emphysema in strangulation, suffocation, and hanging. He failed to find the apoplexies described. The lungs are sometimes anæmic. In healthy young subjects, especially children, the blood-vessels of the lungs often empty themselves after the heart stops. The lungs may therefore be bloodless but emphysematous from the violent efforts to breathe. Page's experiments on the lower animals showed the lungs of a pale, reddish color, and not much distended; occasionally a few dilated air cells were seen toward their anterior borders, and small hemorrhages over the surface. His experiments appear to show that subpleural ecchymoses occur as a result of violent and repeated efforts to breathe. Among other experiments he stopped the mouth and nostrils of a young calf long enough to excite violent efforts at respiration; it was then instantly killed by pithing. The lungs were found pale red, not congested, but showing subpleural ecchymoses. Page believed that these were due to the changed relation between the capacity of the thorax and volume of the lungs. Liman found these ecchymoses in cases of strangulation, hanging, drowning, poisoning, hemorrhage, and œdema of the brain in the new-born, etc. He failed to find them in some cases of suffocation. He believes them due to blood pressure from stasis in the blood-vessels. Ssabinski made many experiments on dogs and cats to ascertain the presence or absence of subpleural ecchymoses in strangulation, drowning, section of pneumogastrics, opening of pleural sacs, compression of chest and abdomen, closure of mouth and nose, burial in pulverulent materials, etc. Similar hemorrhages may appear on the mucous and serous membranes; on the respiratory, digestive, and genito-urinary tracts, and pleuræ, pericardium, and peritoneum, membrane of brain, and the ependyma. They are sometimes minute and stellate, at other times irregular in shape; many are bright-colored. According to Tardieu, the punctiform ecchymoses are rarely present except in suffocation. Maschka, in 234 cases of asphxyia, found the lungs congested 135 times, anæmic 10, and œdematous 42. He thinks the subpleural ecchymoses are valuable signs of asphxyia.

Page experimented on six kittens, strangling three by the hand, the other three by ligature. The results of the post-mortem examinations were nearly similar. The veins were full of dark fluid blood; the right cavities of the heart were similarly gorged, the left empty; lungs pale red, not congested nor distended. Brain normal. The differences were in the lungs: in the first series there were many small, irregular, circumscribed, dark-red ecchymoses scattered over the general surface; in the second a small number of bright-red ecchymoses somewhat larger than a large pinhead.

The bronchial tubes are usually full of frothy bloody mucus, and the mucous membrane is much congested and shows abundant ecchymoses.

In *hanging* the condition of the lungs and heart varies according to whether death is due to syncope or to asphyxia. Ogston found in 22 cases that the lungs were expanded in 1 and collapsed in 2. Harvey says the lungs are congested in over seven-eighths of the cases, emphysematous in a few, and subpleural ecchymoses present in a few. Patenko experimented on dogs by hanging them; when the constriction occurred after expiration, the lungs were congested; after inspiration, not congested. In the first case the blood flows from the periphery to the heart and thence to the lungs, but cannot flow from the lungs because of the difficult circulation in the dilated pulmonary vessels and deficiency of intrathoracic pressure. There is in both cases cerebral congestion in the region of the bulb. Tardieu holds that punctiform ecchymoses and apoplexies do not occur in hanging unless suffocation has preceded. Pellier, however, found these ecchymoses 14 times in 22 cases. He says that the lesion is not characteristic of suffocation, and quotes Lacassagne, Grosclaude, Dechoudans, Vicq, Chassaing, and Legroux to the same purpose. Hofmann says that the ecchymoses are relatively rare in adults. Maschka found them 18 times in 153 cases.

In *asphyxia* the right side of the *heart*, especially the auricle, is usually full of dark fluid blood due to the mechanical impediment to the passage of blood through the lungs. If the heart continues to beat after respiration has ceased, the right ventricle is commonly well contracted like the left cavities and nearly empty, the lungs being much congested. Sometimes the left cavities of the heart contain blood. This would most likely occur if the heart should stop in diastole. Sometimes clots are found in the right ventricle. Maschka found clots in the heart 25 times in 234 cases of asphyxia. Harvey states that in *hanging* the presence of serum in the pericardium seems more a matter of time elapsed after death than anything else. But it is found much oftener in strangulation than in hanging. The difference is explained by the comparative slowness of death in strangulation. Harvey finds that in about one-half the cases if the body is fresh the right side of the heart, pulmonary artery, and venæ cavæ are full of dark fluid blood, the lungs being also much congested, and the signs of death by asphyxia well marked. When blood is found in both sides of the heart, it is probable that death is due to neuro paralysis. When decomposition is advanced all the cavities are often empty. Taylor says that if the examination is delayed several days the distention may not be observed.

In *asphyxia* the *external generative organs* are sometimes congested; erection of the penis may have taken place and have persisted. The vagina may be moist. Tardieu, Devergie, and Casper deny that these appearances are usual. In about one-fourth of the cases of *hanging* the genital organs are congested. The penis is large and more or less erect; seminal fluid, generally prostatic and sometimes mixed with blood, is often expelled. The fluid may pass only into the urethra and it may be necessary to press the urethra to secure it. The clitoris may be found erect and there may be a sort of menstrual flow. Orfila showed by experiment that swelling of the sexual organs and emission of semen can be produced after death in those who have been suspended during life. The flow of semen is found in all kinds of death from violence. Roth, in 39 cases of hanging of men, found the penis enlarged 18 times and ejaculation in 19. Hackel found the penis swollen in 13 per cent. of cases of asphyxia. Erection may come on soon or late, even days after death. Involuntary discharges of urine, fæces, and seminal fluid may occur in all kinds of violent death. There is nothing characteristic in their appearance. Tardieu found them, however, but twice in 41 cases of hanging. Roth, in 49 cases, found discharges of fæces in 17 and of urine in 4; in 15 cases, not noticed.

Harvey mentions a case in which internal piles had burst and there were stains and clots of blood about the perineum and anus. In such cases without careful examination there would naturally be a suspicion of violence.

The *abdominal organs* are generally darkly congested in *asphyxia*, although Maschka denies this for the liver and spleen. The congestion of the viscera generally is doubtless due largely to the prior congestion of the lungs and engorgement of the heart. In hanging, the stomach is often much congested, and this fact might sometimes suggest the possibility of poisoning. The liver, spleen, and kidneys are usually much congested; Hofmann says that this occurs in the kidney only when the body has been hung a long time.

Maschka considers the rounded pinhead ecchymoses of the inner surface of the *scalp* and *pericranium* valuable evidence of asphyxia. The *brain* and membranes are sometimes congested, occasionally apoplectic. Maschka found congestion of brain and membrane 48 times, and anæmia 30 times in 234 cases. In hanging, the brain is rarely much congested. In 101 cases Remer found hemorrhage but once, and in 106 cases Casper failed to find it. Tardieu says the brain is oftenest anæmic. If, however, the body is cut down and placed horizontally, the blood-vessels of the brain may fill up. Evidence may be found in the brain suggesting insanity and therefore an explanation of a probable suicide. Harvey says that hemorrhages in or about the brain are found in a much larger proportion of cases of hanging in India than in Europe. "No common condition likely to cause extravasation is apparent, only one man being noted as plethoric, but in many the rope seemed to have been very tight." Wilkie reports a judicial hanging in which a man, aged about twenty-five, fell about three and one-half feet; a recent clot was found in the brain. The experiments of Brouardel of hanging rabbits showed the brain anæmic.

The conjunction of the following appearances would suggest that the hanging has been of some duration: lividity of face, congestion and prominence of eyes, dryness of skin under the ligature, deep furrow, congestion of sexual organs, swelling and lividity of lower limbs, hypostatic congestion of lungs.

Page experimented on a young cat and young dog; both were hung in the same way. Examination of the cat showed the veins generally engorged; sublingual veins much engorged; tongue protruded slightly and much swollen; no frothy mucus in bronchi. In the dog the tongue did not protrude and was not swollen; right cavities of heart contained blood, left empty; brain and other organs normal. In the cat the lungs were uniformly congested, dark red; no ecchymoses. In the dog the lungs were much distended, posterior borders mottled violet; emphysematous patches on surface; no apoplectic effusions; subpleural ecchymoses bright red, irregular, clearly defined in outer surface, most numerous toward the roots and on the lower lobes.

Pellereau gives an account of hanging as seen by him in warm climates. He had not seen the elongation of the neck described nor the erection of the penis, subconjunctival ecchymoses, fracture of larynx, rupture of walls of carotid artery, subpleural ecchymoses, nor fracture of vertebræ. He always found a mark on the neck; the left cavities of the heart always empty, the right always full of black blood. Mackenzie says that in 130 cases of suicidal hanging the protrusion of the tongue between the teeth, the open and protruding eyes, clinched hands, and blue nails were very frequent; the tongue was found bitten many times; there were urethral and rectal discharges and rupture of the carotid artery. The penis was found erect several times. The hyoid bone was fractured 24 times in 93 cases. In no case was the larynx or vertebra fractured. In 73 cases ropes were used; in 30, portions of clothing. The marks of ropes were always well defined, indented, and parchment-like; the marks of soft ligatures faint and reddish. In no case were the muscles of the neck, the larynx, trachea, or large bronchi injured, and in none was there subcutaneous hemorrhage or blister.

Hofmann says that the rupture of the carotid in hanging is always transverse, may be simple or multiple, and may occur in suicides; more apt to occur when the ligature is thin. Lesser tabulated 50 fatal cases of suicidal hanging; in 29 he was satisfied that the hanging occurred during life; in 3 of these the skin of the neck alone showed any lesion; there was a double mark, the skin being otherwise bloodless; in 5 the deeper soft parts were the only ones affected; in 3 the skin showed lesions, the deeper soft parts none, but either the hyoid bone, larynx, or vertebræ were involved; in 12 the skin showed no mark, but the deeper soft parts and either the larynx or hyoid bone were involved; and in 6 the hyoid bone only or the bone and larynx were injured. In the remainder it was not possible to say that the hanging occurred during life. In two cases there were no marks at all; in 9 there were changes in the skin; in 4, changes in the skin and deeper parts; in 2, changes in the skin, deeper parts, and hyoid bone or larynx; in 3, changes in the skin and hyoid bone, or larynx, or both. In 14 of the 50 cases the hyoid bone was fractured; in 20, the larynx; and in 1, the vertebræ. The common carotid arteries were injured in 6. The number and severity of the lesions bore no constant relation to the thickness of the ligature nor to the force used, but rather to the position of the body.

Daniel S. Lamb.

STRAWBERRY. See *Rosaceæ*.

STRONTIA MINERAL SPRING.—Baltimore County, Maryland.

Post-Office address, 305 and 307 Exchange Place, Baltimore. No hotel near springs.

This spring is located about nine miles from the heart of the city of Baltimore. It is reached by the Green Spring branch of the Northern Central Railroad to Strontia Spring station, thence one-half mile to springs. The elevation of the locality is about six hundred feet above the sea-level, and the average summer temperature is about ten degrees lower than that of Baltimore. An analysis of the spring water made in 1887 by Prof. W. W. Simon, of Baltimore, resulted as follows: One United States gallon contains (solids): Potassium nitrate, gr. 2.71; sodium nitrate, gr. 0.83; sodium chloride, gr. 7.59; magnesium chloride, gr. 3.91; calcium chloride, gr. 20.67; calcium bicarbonate, gr. 3.93; strontium sulphate, gr. 0.13; strontium bicarbonate, gr. 1.08; iron bicarbonate, gr. 0.51; alumina, gr. 1.08; silicic acid, gr. 1.19; and traces of phosphoric acid, iodine, ammonia, and organic matter. Total, 43.54 grains. Gases: Oxygen, cub. in. 0.48; nitrogen, cub. in. 0.71; carbonic acid, cub. in. 2.04.

Since 1876, when the properties of this water were discovered, it has acquired a wide reputation in the treatment of sea-sickness, dyspepsia, gout, rheumatism, and diabetes. It is used commercially and as a table water. It has found its way into many of the leading hotels, clubs, and cafés of New York, Baltimore, and other cities. It is a saline-calcic, and has tonic, diuretic, and alterative properties. It is probable that the considerable quantity of strontium in the water modifies its action to some extent, but in what way cannot be explained in the present state of our knowledge.*

James K. Crook.

STRONTIUM.—*General Medicinal Properties of Compounds of Strontium.*—Salts of strontium resemble those of calcium in being practically non-poisonous to the human system and in tending to improve nutrition. Also they are of low diffusion power, and accordingly are comparatively slow of absorption. Strontium has been proposed in medicine as affording a base for medicinal salts that is non-poisonous and even agreeable to the stomach. Accordingly strontium has been suggested for

* Some of the strontium salts are now used in the treatment of epilepsy, diabetes, parenchymatous nephritis, muscular and subacute articular rheumatism, and acute gastritis.

the basic carrier of bromine, iodine, and salicylic acid, and the bromide, iodide, and salicylate of the metal are considered preferable to the corresponding potassium and sodium salts, because better borne by the stomach. The United States Pharmacopœia recognizes strontium bromide and iodide (see *Bromides* and *Iodides*), and also the *lactate*, which latter salt will be considered here, since its effects are not due specifically to its acid radical.

Strontium Lactate.—The salt is official in the United States Pharmacopœia under the title *Strontii Lactas*, Strontium Lactate. It occurs as a white, granular powder, permanent in the air. It is odorless, with a bitterish, salty taste. It dissolves in about four parts of cold water, and freely in boiling water and in alcohol. Strontium lactate is a harmless salt, whose use in medicine is because of a reputation, in chronic Bright's disease, for diminishing the albumin in the urine and improving the patient's condition generally. In the form of the disease accompanying rheumatism and gout, it is praised, but it should not be used in conditions of acute inflammation with high fever. In albuminuria from heart disease, also, the medicine is reported to diminish the albumin. The drug may be given in doses of from 1.3 to 2 gm. (gr. xx. to xxx.) or more, two or three times daily. *Edward Curtis.*

STROPHANTHUS.—(*Kombe, Arrow Poison, Inée, Onaye*, etc.) The dried ripe seed of *Strophanthus Kombe* Oliver, and perhaps of other species (fam. *Apocynaceæ*), deprived of its long awn. The British Pharmacopœia names the plant as above, under the title *Strophanthi Semina*. The German, under the title *Semen Strophanthi*, says "very probably from *Strophanthus Kombe*." The United States Pharmacopœia, because at the time of its revision ten years ago information on this point was very imperfect, specifies the seeds of *S. hispidus* De C., which we now know to be incorrect.

The strophanthus plants are woody climbers of tropical Africa, where an extract of the seeds of several of them is used as an arrow poison and in other ways for poisoning. The seeds occur in lanceolate or lance-ovoid follicles, of which two develop from each flower. These are 15 to 30 cm. (6 to 12 in.) long, and about a sixth or a fifth as thick. They are densely filled with seeds, the bodies of which are embedded among the long, white, plumose awns. The seeds are imported either in the pods or after removal, and in the latter case either with or freed from their awns. They should be imported and reach the consumer in the pods, since this permits the identification of the contents by the testing of one seed from each pod. This is an almost necessary method of examination, since good and poor varieties of seeds so closely resemble one another that an admixture is very difficult to detect in the cleaned seeds. Some varieties are practically inert, while others are extremely powerful, and in different ways, so that the employment of correct methods of identification of the seeds is of vital importance to the patient. Although all parts of the plant are bitter, the seeds alone have been investigated.

Description.—Good strophanthus seeds are of a peculiar pale greenish-brown color, and are densely covered with very fine, closely appressed silky hairs. This appearance of the surface constitutes the best guide to selection, outside of chemical examination. Two classes which should be rejected are those of a distinctly brown to dark brown color, and those of a very pale yellowish or yellowish-white, without greenish tinge, and the hairs coarse and more or less roughening the surface by their irregular projection. Strophanthus seeds are about 1.25 cm. or a little more in length, and one-fourth to one-third as thick, lanceolate, obtuse at the base, gradually pointed at the summit; they are somewhat flattened or even a little hollowish on one side, and have a narrow ridge running along the other, and are often warped or even semi-twisted. They are brittle, the fracture whitish and oily, the kernel consisting of rather long cotyledons, enclosed in sparse albumen. They have a slight odor and an extremely bitter taste. On being crushed and tested with strong sulphuric acid, a green color should quickly develop, due to the reaction of the strophanthin, which is mostly contained in the albumen or endosperm. In this way, the testing of a single seed taken from a pod determines the identity and quality of the entire contents. However, should the test fail, it should be repeated with one or two more seeds from other parts of the pod, as individual seeds sometimes occur which are imperfect.

Constituents.—With various ordinary constituents of seeds, strophanthus contains two or three bodies of therapeutical interest. The important medicinal constituent is two to three per cent. of strophanthin, considered below. The properties of the twenty-five to thirty per cent. of fixed oil are not known with certainty. We should expect it to be inert, but indications of its irritating and toxic properties are not wanting. On the other hand, these are more likely due to contained substances than to the oil itself. Some species of the seeds contain the very poisonous glucoside *pseudostrophanthin*, and, since the commercial seeds are almost always mixed, it may be the presence of this in the oil which makes the latter poisonous. The poisonous properties referred to are not the same as those of over-doses of strophanthin, since the greater toxicity is not accompanied by a correspondingly greater cardiac tonic effect, but often by a lesser one. *Kombic acid* is present, but its properties have not been investigated, and the name has apparently been applied to more than one substance. Other constituents reported are uncertain, since the specific identity and freedom from admixture of the seeds analyzed has not been determined. *Strophanthin* is a crystalline glucoside, usually appearing amorphous, as a fine white powder, soluble in alcohol and water, especially the latter, insoluble in ether and chloroform. The formula usually given ($C_{31}H_{48}O_{12}$) cannot be considered as fully established. Upon decomposition, it yields *strophanthidin*. Commercial strophanthin is very rarely, if ever, pure.

Action and Uses.—The therapeutical action of strophanthus is that of strophanthin, and is directly and almost wholly referable to the heart. It is commonly stated as being identical with digitalis, but the statement is very misleading, unless certain differences in other directions are carefully considered. Although its direct action is almost identical with that of digitalis, the resultant effect is quite different, owing to the absence of those complications from arterial effects which result from the use of digitalis. Strophanthus does not contract the arteries, hence none of the gain from cardiac stimulus is counteracted, and there is none of that danger of damming back the blood upon an incompetent heart, which sometimes exists when digitalis is used. Another very important difference between the two is the great promptness with which strophanthus gets to work, its effects being observed in from a third to a half of the time required for digitalis. This is partly due to its purely cardiac action, partly to the fact that the absorption of strophanthin is very rapid. Strophanthus strengthens and slows the heart beat, prolonging the diastolic period, and it is especially valued for its power of restoring rhythm to an irregular beat. It is thus especially useful when a very prompt action is desired, and also where cardiac action is weak relatively to arterial. Even in those cases in which digitalis is properly called for, a great gain may be secured by giving an initial dose of strophanthus, following it with the digitalis.

On the other hand, the effect of strophanthus is far less prolonged than that of digitalis, and is not cumulative like the latter. Hence, small doses, repeated at frequent intervals, is the rule for the administration of strophanthus. Even in this way its effects cannot be prolonged like those of digitalis, for the beneficial effects first seen soon decrease. It cannot therefore be regarded, like digitalis, as a mainstay, but rather as an emergency remedy. The effect upon the stomach is far less irritating than that of digitalis, hence there is not the same tendency to emesis. The same principle applies to the kidneys, the local effect upon the latter being very slight. Yet strophanthus is an indirect diuretic, through increased cardiac action. It is often even more strongly diuretic than digitalis, owing probably to the absence of obstruction by vascular contraction. For the same reason, the danger of damage in cases of complication with organic kidney disease is wanting. Strophanthus is also a safer and more comfortable remedy for children.

ADMINISTRATION.—Owing to the facts stated above, it is not so difficult to secure genuine and pure strophanthus seeds, and therefore corresponding preparations of them, as it is to secure pure strophanthin, and the former are to be preferred in all ordinary cases. The official preparation is a five-per-cent. tincture of the seeds, made with sixty-five-per-cent. alcohol, and the dose ranges from three to ten minims. When larger doses are required, it is usually because the very inferior "brown seeds" have been employed. These are several times cheaper and they have been used extensively even by some large manufacturers. On the other hand, a preparation of the "white seeds" will prove irritating and will act as a poison without a corresponding increase in therapeutic effect. Strophanthin may be given in doses of 0.0006 to 0.0012 gm. (gr. $\frac{1}{100}$ to $\frac{1}{50}$). *Henry H. Rusby.*

STRUMA.—This term has been used in a general way to indicate a swelling or protuberance in any part of the body, but particularly with reference to enlargements of the lymph glands and the thyroid gland. Since such enlargements are most frequently due in the case of the lymph glands to tuberculosis, and in the thyroid to goitre, the word struma has come to be largely used as a synonym for both scrofula and goitre. Further, it has been applied to enlargements of the lymph glands other than those of a tuberculous nature, also to enlargements of the thymus, to enlargements of the kidneys and suprarenal bodies due to tumors arising from adrenal tissue, and in rare cases to splenic enlargement. Such a widespread application of the term, as well as its failure to convey any definite idea concerning the etiology or pathological nature of the conditions so designated, would appear to be sufficient reason for its abandonment, and in pathology it is gradually falling out of use. At present there occur in the literature the following different applications of the term, given in the order of frequency of usage.

1. As a synonym for *scrofula*. So common is this usage in the literature of a generation ago that the term strumous has come to be used almost entirely in the sense of scrofulous (see *Scrofula* and *Tuberculosis*).

2. As a designation for *goitre* or *bronchocele*. At the present day the term struma is probably more frequently applied by clinicians to enlargements of the thyroid than to tuberculous enlargements of the lymph glands, and in this connection a great number of modifying terms occur in the literature: *struma colloides*, colloid goitre; *struma gelatinosa*, also applied to colloid degeneration of the thyroid; *struma hyperplastica*, an enlargement of the thyroid due to hyperplasia either of the parenchyma (*s. parenchymatosa*) or of the interstitial connective tissue (*s. fibrosa*); *struma cystica*, colloid degeneration of the thyroid with cyst formation; *struma follicularis*, synonym for colloid, hyperplastic, or parenchymatous struma; *struma mollis*, soft or colloid goitre; *struma petrosa*, hard or hyaline goitre; *struma cystica petrosa*, cystic goitre with hyaline change in the interstitial connective tissue; *struma cystica ossea*, cystic goitre with calcification in the hyaline connective tissue; *struma hyperplastica vascularis* or *aneurysmatica*, a vascular goitre with hyperplasia of the connective tissue; *struma aneurysmatica, pulsans* or *cavernosa*, vascular goitre with dilated vessels; *struma hypertrophica simplex*, simple colloid or parenchymatous goitre; *struma intrauterina congenita*, a simple parenchymatous hyperplasia of the thyroid in the new-born as distinguished from the swelling of the thyroid region in face presentations; *struma congenita*, congenital goitre; *struma maligna*, sarcoma or carcinoma of the thyroid; *struma amyloidea*, supposed amyloid goitre, incorrectly applied to hyaline goitre; *struma glandulosa*, enlargement of a portion of the thyroid separated from the main gland; *struma endothoracica*, enlargement of isolated or accessory thyroid tissue or of a deeply lying thyroid in the anterior mediastinum (retrosternal or retroclavicular struma); *struma chlorotica*, the enlargement of the thyroid frequently seen in chlorosis, and sometimes, when associated with prominence of the eyeballs, mistaken for exophthalmic goitre; etc.

3. *Struma lymphatica*, a synonym for *status lymphaticus* or *lymphatic constitution* (see *Status Lymphaticus*).

4. *Thymus struma*, the enlargement or persistence of the thymus after the period at which this organ usually undergoes retrograde change. As this condition is associated with lymphatic struma, it is usually included under that designation.

5. *Strumæ lipomatodes aberratæ renis*, or *hepatis*, *strumæ lipomatodes suprarenales*, *adrenal struma*, are terms applied to the tumors of adrenal tissue arising within the kidney or its capsules, in the adrenals, or in the neighborhood of these organs or in the liver (see *Hypernephroma*).

6. The vicarious use of struma to indicate enlargements in other parts of the body, as of the spleen, bones, etc., may in the majority of cases be traced to the influence of the association of the term with scrofula or diathesis.

Aldred Scott Warthin.

STRYCHNINE.*—*Strychnina* ($C_{21}H_{22}N_2O_2 = 333.31$). "An alkaloid obtained from nux vomica, and also obtainable from other plants of the family *Loganiaceæ*."—U. S. P.

The origin of strychnine has been fully discussed under *Nux Vomica*. Its extraction from the seed is accompanied by much difficulty, owing to its strong retention in the cells of the horny albumen. Naturally, various methods have been employed for overcoming this difficulty. The seeds are either powdered in their original condition, or first subjected to a steaming process and then dried. The strychnine can be dissolved out by alcohol in the form of its natural salt or by water acidulated with hydrochloric acid. The concentrated and filtered solution is then treated with an alkali, such as acetate of lead or lime, to decompose the alkaloid, which is then precipitated and purified. The principal impurity liable to exist is brucine, the tests for which are indicated in the following description:

Colorless, transparent, octahedral or prismatic crystals, or a white, crystalline powder, odorless, and having an intensely bitter taste perceptible even in highly dilute (1 in 700,000) solution. Permanent in the air.

Soluble, at 15° C. (59° F.), in 6,700 parts of water and in 110 parts of alcohol; in 2,500 parts of boiling water and in 12 parts of boiling alcohol. Also soluble in 7 parts of chloroform, but almost insoluble in ether.

When heated to 268° C. (514.4° F.) strychnine melts. Upon ignition it is consumed, leaving no residue.

Strychnine has an alkaline reaction upon litmus paper.

If a minute quantity of strychnine be dissolved in about 0.5 c.c. of concentrated sulphuric acid on a white porcelain surface, and a small crystal of potassium dichromate slowly drawn across the liquid with a glass rod, there will be produced at first, momentarily, a blue color, which quickly changes to purplish-blue, then gradually to violet, purplish-red, and cherry-red, and finally to orange or yellow.

On dissolving 0.02 gm. of strychnine in 2 c.c. of nitric acid (specific gravity 1.300), in a small test-tube, the acid should not turn more than faintly yellow (limit of *brucine*).

ACTION AND USES.—Strychnine is one of the most intense and energetic of poisons, acting deleteriously upon nearly all forms of animal and vegetable life. There are, however, considerable differences in the susceptibility of different creatures to its influence, and in general those which are destitute of or have but a primitive nervous system withstand it better than the higher organisms.

* Also spelled strychnin.

On this account, its antiseptic and antizymotic properties, though distinct, are decidedly weaker than those of quinine and some similar substances; for this reason and because of their being but a little poisonous, the latter are far more desirable of employment for such purposes.

Absorption and Elimination.—Strychnine is promptly absorbed from the mucous membrane and rather freely from abraded surfaces and from the subcutaneous tissue. It circulates in the blood as strychnine and is thus eliminated, though a small part of it is oxidized. Elimination is principally by the kidneys, to a considerable extent through the saliva, and to a slight extent through most of the other channels. This prompt absorption and slow elimination render it one of the most notoriously cumulative drugs, a fact which is considered more at length in the article on *Nux Vomica*. Tolerance, by its continued use, is not much increased.

Local Action.—The disinfectant properties of strychnine are noticed above. It exerts a prompt though mild stimulant action upon the tissues with which it comes into contact. In the mouth and stomach it acts like the ordinary simple bitters, in promoting the appetite, but, unlike the most of them, its presence in the stomach promotes rather than inhibits digestion, so that it is probably the most valuable of all stomachic bitters, especially in view of the fact that its local effects are strongly reinforced as soon as absorption begins. In the intestine, its local effect is to stimulate peristalsis, making it a valuable laxative, and this effect is again reinforced by its systemic action through the spinal centres.

Upon the heart the operation is somewhat different, since the local effect of stimulating the rate, through its action on the muscle, is just about counteracted by its systemic effect upon the vagus centres, which checks such increase.
